2D random metal networks possess unique electrical and optical properties, such as almost hundred percent optical transparencies and low sheet resistance, which are closely related to their disordered structure and may be exploited in various applications. Here we present a detailed experimental and theoretical investigation of their plasmonic properties, revealing Anderson (disorder-driven) localized surface plasmon (LSP) resonances of very large quality factors and spatial localization close to the theoretical maximum. The LSPs typically consist of multiple field hotspots with a well-defined correlation distance and couple to electromagnetic plane waves. Moreover, they disappear above a geometry-dependent threshold at ca. 1.6 eV in the investigated networks, explaining their large transparencies in the optical spectrum.

I. INTRODUCTION

Disordered metallic nanostructures, especially out of Au and Ag, are studied since decades for their unique mechanical, electric, chemical and optical properties, and ensuing applications such as flexible electrodes for neural implants [11] and monitoring of blood vessels [2], electromagnetic chemical vapor and gas sensors [3], etc. [4]. One of their most intriguing properties, however, is the emergence of strongly enhanced and localized electromagnetic fields. These were first observed in so-called random dielectric thin films (also referred to as semi-continuous metal films) [5–7], which occur upon Volmer-Weber-type growth of metallic thin films. Following the Ioffe-Regel criterion [8], Anderson localization (AL) of (classical and quantum) waves in disordered systems can occur in the limit of strong resonant scattering when the mean free path becomes equal or less than the wavelength. Accordingly, various articles discuss the observed emergence of localized surface plasmon (LSP) modes in disordered systems in the context of AL employing different localization measures and theoretical frameworks (for quasistatic description see [9] and references therein, for fully retarded see [10–11]). Average quantities such as energy transport or effective dielectric functions may be well described with the help of renormalization techniques and sophisticated self-consistent theory of AL [11]. Note, however, that persisting theoretical challenges are emerging in the description of anisotropic and lossy media, and in the description of the local fluctuations, which may be ultimately traced to the vectorial and non-hermitian character of the plasmon dynamics.

Meanwhile, AL of classical optical and infrared fields has been observed in a variety of related systems, such as nanoparticle (NP) aggregates [12] and lithographically produced cavities [13–14]. Moreover, various applications such as Surface Enhanced Raman Spectroscopy (SERS) [5–15], the effective generation of non-linear optics on the nanoscale (e.g., four wave mixing, non-linear absorption, harmonic generation) [16], random lasing [17–18], and bistable optical transistor [19], have been discussed and partially realized. Note, however, that persisting challenges in engineering the network geometry (e.g., percolation threshold) and the limited substrate choice of the semicontinuous metal films still hamper these efforts.

Very recently, the development of a novel synthesis route allowed for the synthesis of large scale 2D Au networks with significantly reduced mass thickness (compared to the semicontinuous metal films), deliberately tunable coverage and fractal dimension [20], thereby overcoming some of the above limitations. In the following, we experimentally demonstrate the emergence of disorder-driven LSP resonances in this novel type of Au networks. We demonstrate very large quality factors of ≈ 8 of these modes and show that the localization mechanism can be described in terms of AL by comparison with simulations allowing to deliberately switch on loss, retardation, and disorder. In contrast to the previous studies on random dielectric films, we employ high-spatial resolution Scanning Transmission Electron Microscopy Electron Energy-Loss Spectroscopy (STEM-EELS) plasmon mapping [21], which allows to resolve the LSPs at nanometre length scale and a direct correlation of the localization position with the underlying Au network structure.

II. EXPERIMENT

2D Au networks of varying fractal dimension and coverage (0.310 - 0.544) have been synthesized following the procedures described in Ref. [20]. Following the initial synthesis step and after the evaporation of the organic solvent the networks were transferred to a TEM-grid by carefully pressing the substrate onto the aqueous solution. Then, the substrate was washed with Ethanol (EtOH) (see Fig. S1 in the Appendix for an exemplary
Spatially resolved EEL spectra (so-called spectrum images) $\Gamma(r_\perp = (x, y), \omega)$ of a collection of subareas of the network, which are proportional to the integral of the induced $z$-component of the electric field along the beam direction $\left(\Gamma \propto \int dz \mathbb{R}\left\{e^{-i\omega z/v}\tilde{E}_z(r_\perp, z, \omega)\right\}\right)$ with energy-resolution of 60-70 meV were recorded while scanning a sharply focused probe of electrons with 80 keV kinetic energy over the sample in a probe-corrected Transmission Electron Microscope (see Fig. 1, Appendix B and refs. [21, 22] for a description of the method, the setup and the various processing steps). For analyzing the spatial localization of the LSP modes we corrected for elastic scattering absorption (i.e., scattering of electrons into large scattering angles) by normalization of the point-wise collected spectra by the overall intensity of each individual spectrum $\left(\Gamma_n(\omega, r_\perp) = \Gamma(\omega, r_\perp)/\int \Gamma(\omega, r_\perp) d\omega\right)$.

Examples of typical spectra, shown in Fig. 2a, reveal the presence of spectrally localized SP modes of excitation energies $\hbar\omega$ ranging from approximately 0.3 eV (ca. 73 THz) to 1.6 eV (ca. 387 THz). Most remarkably, the quality factor $Q = \omega/\Delta\omega$ given by the ratio of the energy of a particular mode and its energy width (FWHM) frequently reaches values in the range of 10, which comes very close to the theoretical achievable maximum in Au limited by the comparatively large imaginary part (loss) of its bulk dielectric function (see Appendix C). Displaying the spatial slices of the spectrum image datacube (Fig. 2b, c) reveals the spatial localization of the SP modes (so-called hotspots), where the magnitude of the localization clearly increases towards higher excitation energies. Additionally, we observe that the maximally localized spin-orbit split-off mode (in the vicinity of the 1.6 eV threshold) are always centered around the underlying Au network stripes. In the region between approximately 1.6 eV and the surface plasmon cut-off frequency $(\hbar\omega_{\text{cut-off, Au}})$ of Au at 2.4 eV only fundamental LSP modes of the Au-vacuum interface of no mutual hybridization and hence field enhancement are observed.

III. ANDERSON LOCALIZATION

By breaking any translational symmetry, the self-affine Au networks support localized modes, which are square integrable in the sense that $\int_{-\infty}^{\infty} E(r)^2 d^3r < \infty$, may be assigned a position (centre of mass) and form a discrete spectrum. To measure the localization from the EEL spectrum images, we employed two different localization measures frequently used in the context of AL [13]: (I) the azimuthally averaged $(\langle \ldots \rangle_\varphi)$ autocorrelation $R(\varphi, \omega) = \langle \int_{-\infty}^{\infty} \Gamma_n(r_\perp + r_\perp', \omega) - \Gamma_n(r_\perp', \omega) \rangle d^3r_\perp'$ with a certain energy interval (midpoint $\omega$) corresponding to the energy resolution of the experiment, and (II) the inverse second moment of the spectrum image $p(\omega) = 1/\int_{-\infty}^{\infty} \Gamma_n^2(r_\perp, \omega) d^3r_\perp$ within an energy interval. The latter is closely linked to the so-called inverse participation ratio and has been shown to reflect localization rather robustly independent of absorption and the actual function nature of localization (e.g., exponential or algebraic) [10].

By exhibiting a characteristic central peak with corresponding peak width $\xi$ (blue region in Fig. 3a, within the Full Width at Half Maximum (FWHM)) the autocorrelation confirms the localized nature of the surface plasmon resonances (presence of hotspots). The peak width $\xi$ decreases with energy with no significant dependency on the network properties. Moreover, a significant second maximum indicates the presence of somehow correlated field maxima at approximately 120 nm distance. Note, however, that the uncorrelated nature of the point-wise recorded EEL spectra does not allow a definite statement about the nature of the correlation between different hotspots at this stage.

The increasing localization of the LSPs is further corroborated by the inverse participation ratio $p$ (see Fig. 3b, d), which increases toward higher energies until approximately 1.6 eV (i.e., the same energy where localized modes disappear).

In order to further analyse the observed localization behaviour, we conducted numerical simulations of surface plasmon resonances in which strength of disorder, loss and retardation may be deliberately modified. The fully retarded response of the Au network is well described by macroscopic Maxwell's equations taken into account a frequency dependent inhomogeneous dielectric function $\epsilon_{\text{Au}}(\omega)$, i.e., $\nabla \times \nabla \times E(r, \omega) - k^2 \epsilon(r, \omega) E(r, \omega) = -i\frac{e^2}{c^2}\mathbf{j}_{\text{ext}}(r, \omega)$. Here $\mathbf{j}_{\text{ext}}$ denotes the external current.
(e.g., electron beam in case of EELS) and \( k = \omega/c \) the wave number of the free photon. From the prefactor of the second term on the left it is readily observed that the impact of disorder increases quadratically with \( \omega \), which agrees well with the experimentally observed increase of localization. Note, furthermore, that this behaviour is markedly different from quantum AL (e.g., of single electrons), where such an "intrinsic" amplification of disorder toward higher frequencies is absent.

In order to circumvent the computationally demanding (if not unfeasible) computation of the above partial differential equation on a large Au net, we solved the inverse problem of interacting randomly distributed oblate Au NPs (representing the holes of the network) of inverse problem of interacting randomly distributed oblate Au NPs (representing the holes of the network) of random lateral radius and same thickness as the network yielding the same (inverse) coverage like the Au network. This approach exploits the qualitative similarity between the plasmonic response of the complementary and the original system due to a generalized Babinet principle \([23][25]\). The latter holds in the limit of thin samples (in comparison to the photon wavelength) consisting of perfectly conducting material \([24]\). Both conditions are satisfied well by the investigated 2D networks in the evaluated frequency range (\( \omega \) well below the material’s plasma frequency \( \omega_p \)). Restricting the interaction between the NPs to the dominant dipole coupling leads to further simplification, i.e., the following discrete equation system for the particle’s polarization vectors \( \mathbf{P}_i \): 

\[
\mathbf{P}_i(\omega) - \alpha_i \sum_{j \neq i} \mathbf{G}_{ij}(\omega) \mathbf{P}_j(\omega) = \alpha_i(\omega) \mathbf{E}_{\text{ext},i}(\omega)
\]

with the retarded dipole interaction \( \mathbf{G}_{ij}(\omega) = \frac{1}{\pi \epsilon_0} \left\{ \frac{\mathbf{1}}{r_{ij}} \left( \mathbf{I}_3 - \mathbf{r}_{ij} \otimes \mathbf{r}_{ij} \right) + (1 - i k r_{ij}) \left( \frac{3 \mathbf{r}_{ij} \otimes \mathbf{r}_{ij} - \mathbf{I}_3}{r_{ij}^3} \right) \right\} e^{i k r_{ij}}.
\]

Here the indices \( i,j \) denote the individual NPs, \( \mathbf{I}_3 \) the 3 \times 3 identity matrix, \( \alpha_i \) the polarizability tensor of a prolate NP, \( \mathbf{E}_{\text{ext},i} \) the external electric field (photonic or due to external charges), and \( \mathbf{r}_{ij} \) the unit distance vector between two NPs. Resonant modes occur when \( (\mathbf{I}_3 - \alpha \mathbf{G})^{-1} \) approach zero (i.e., a small external field leads to a large response). In the following, we will determine these modes by solving the corresponding eigenvalue problem \( \mathbf{P} \mathbf{P}_i(\omega) = \alpha_i \sum_{j \neq i} \mathbf{G}_{ij}(\omega) \mathbf{P}_j(\omega) \) and restricting the eigenspace to modes with an eigenvalue \( \mathbf{P} \) close to 1 (resonance condition). Their localization behaviour is then analysed again by computing their azimuthally averaged autocorrelation \( \hat{R}(r,\omega) = \langle | \mathbf{E}_P(\omega, r, r') |^2 \rangle \) and inverse participation number \( \rho(\omega) = \langle \int | \mathbf{E}_P(\omega, r, r') |^2 r^2 dr \rangle \) (both averaged over resonant modes indicated by \( P \)).

Accordingly, the eigensolutions in close vicinity to the resonance condition are localized and exhibit a signifi-
significant correlated excitation of close-by NPs at a distance of approximately 120 nm in excellent agreement with the experiment (Fig. 3a, c). Similarly, the inverse participation ratio increases with energy as observed experimentally (Fig. 3b, d). Moreover, the number of resonant eigenmodes abruptly decreased above 1.6 eV reflecting the experimental observation of vanishing hybridized LSP modes above this threshold (see Fig. 2a).

Having established a good qualitative and partly even quantitative agreement between experimentally observed LSPs in the Au networks and the simulated LSPs in the randomly distributed oblate NPs, we may now draw several conclusions about the localization behaviour: (I) Switching off loss and retardation (Fig. 4d) does not significantly alter the localization behaviour. While the former rules out finite lifetime related localization effects as dominant mechanism behind the observed localization the latter shows that wave interference on short distances below the photon wavelength is the driving force (in correspondence to Ioffe-Regel criterion). Completely switching off disorder, i.e., considering an ordered square lattice of NPs, leads to completely different delocalized mode structure (as well as autocorrelation and inverse participation ratio), i.e., quasi-continuous plasmon bands (not shown) [22], which also proves the disorder as the primary trigger for the observed localization. (II) The presence of the second peak at 120 nm in the azimuthally averaged autocorrelation $R(r, \omega)$ computed from the resonant eigenmodes proves the presence of correlated field hotspots over that distance within single LSP modes (and not independent LSP modes). This implies that the resonant modes are supported by multiple (typically between 2-5, see Fig. 4a) hotspots, which in turn give rise to non-vanishing dipole moments of the LSPs. Indeed, we observe very good agreement between experimental optical transmission spectra and spatially averaged STEM-EELS spectra, thereby demonstrating the coupling of the observed LSPs to electromagnetic plane waves (see Fig. 4b). (III) The disappearance of hybridized localized modes above 1.6 eV independent of loss magnitude is a universal localization effect, which only depends on geometric parameters of the network (i.e., coverage, size of holes, thickness) and not on the material composition.

Indeed, the simulated localization behaviour (including the threshold) in Ag NP assemblies of same coverage agrees very well with that of Au (see red and black curve in Fig. 4d) despite the much broader plasmon band of Ag up to $\hbar \omega = 3.7$ eV. Furthermore, Au NP assemblies of lower coverage exhibit a lower threshold, amongst others (see green curve in Fig. 4d). We therefore attribute the suppression of LSPs in these networks also to a (de-
IV. SUMMARY AND OUTLOOK

Summing up, we showed both experimentally and theoretically that (self-affine) metallic networks of very low mass thickness and coverage support Anderson (disorder- and independent) threshold at ca. 1.6 eV in the investigated networks, which explains their exceptionally large transparency in the optical spectrum.

Unresolved questions pertain to a physical explanation for the observed correlation distance and multi-hotspot character (e.g., by self-consistent AL theory) and a better understanding of how to tune the spectral range of the localized modes. Both aspects are important for envisaged future application of the networks as transparent electrodes or plasmonic sensors.

Appendix A: Synthesis of the Au network

The general synthesis route of the 2D Au networks (see Fig. S1 for an example) is analogous to the literature. At first, the Au NPs were synthesized. Therefore, 0.1 mmol HAuCl₄·3H₂O (Sigma-Aldrich > 99.9 % trace metal basis) was dissolved in 492 ml water and solutions (volumes 2 till 4 ml) of 0.143 mmol/ml NaBH₄ (Sigma-Aldrich, > 96 %) were swiftly added and everything was stirred for 30 min. In one case, the obtained solution was diluted afterwards by adding 100 ml water. The 2D Au network structures were prepared in the following way. Firstly, 200 µl or 400 µl of above synthesized Au NP solution were deposited on cover slips (24 x 24 mm, washed with acetone). Subsequently, the solution was slowly overlaid with 100 µl of a toluene/EtOH (1:1) mixture and the 2D Au network structures formed at the phase boundary. After the evaporation of the organic solvent the structures were transferred to a TEM-grid or an- other cover slip by carefully pressing the substrate onto the aqueous solution. Then, the substrate was washed with EtOH. Transmission spectra were recorded using a Varian Cary 5000 absorption spectrometer.

Appendix B: Plasmon mapping with STEM-EELS

STEM scanning combined with acquisition of EELS spectra was performed in the probe-corrected FEI Titan³ TEM operating at 80 kV acceleration voltage. The microscope was equipped with a Gatan Tridem energy filter and a Wien monochromator, which was optimized to facilitate an energy resolution of 60-70 meV. EELS was performed under a convergence angle of 16 mrad and a collection angle of 3 mrad with an energy dispersion of 0.01 eV per channel. The spectrum images were acquired with a beam current of 120 pA and dwell time of 30 ms. To improve measuring statistics, several (up to 10) repeated spectrum-images were recorded for each dataset followed by the summation of the data accounting for individual spatial drifts. The obtained spectra were corrected for the temporal energy instability of primary electrons through the alignment of the zero-loss peak (ZLP). This peak, prevailing in the low-loss EELS region, was then deconvoluted from the spectra by means of Richardson-Lucy algorithm and ultimately subtracted employing a reference profile collected in a separate run in vacuum. Finally, the energy positions and magnitude of distinct peaks in the low-loss region were fitted using the nonlinear least-squares procedure to determine the quality factors.

Appendix C: Theoretical Limit of the Q-factor

In general the Q-factor of a LSP mode is defined as \( Q = \frac{\omega}{\Delta \omega} \) whereas \( \hbar \Delta \omega \) corresponds to the FWHM of the spectral peak in the loss spectrum. By calculating the Fourier Transform of the damped plasmonic oscillator one finds a Lorentz line shape with FWHM = \( 2 \omega'' \) (FWHM = \( \sqrt{2} - 1 \) in case of the experimentally measured absolute square of the Lorentz line):

\[
\mathcal{F} \left\{ e^{-at} \right\} = \mathcal{F} \left\{ e^{-i \omega' t} \cdot e^{-\omega'' t} \right\} = \sqrt{\frac{1}{2\pi}} \frac{\omega''}{\omega^2 + (\omega - \omega_p)^2}.
\]

Following Fuchs and Kliewer the imaginary part of the complex plasmon angular frequency \( \omega \) can be approximately associated with the Drude relaxation time \( \tau \) of the bulk plasmon and the plasma frequency \( \omega_p \): \( \omega = \omega' + i \omega'' \approx \frac{\omega_p}{\tau} = 0.5 i \frac{\omega_p}{\tau} \). Assuming \( \tau = 5.646 \times 10^{-14} \) s this directly leads to FWHM = \( \Delta \omega = (\sqrt{2} - 1) \frac{\Delta \omega}{\tau} = 30 \) meV. At 1 eV loss energy this corresponds to \( Q \approx 30 \) which represents the theoretical limit unreachable in practice due to loss channels not considered by Fuchs and Kliewer e.g., radiative losses, inter- and intraband transitions, etc. Note furthermore that the experimental determined FWHM is also broadened due to the residual width of the zero loss peak in the EEL spectrum of \( \approx 30 \) meV after the Lucy-Richardson deconvolution. Consequently, the experimentally observed quality factors of the AL localized LSPs are close to the maximum achievable in Au plasmonic nanostructures, which may be further verified by comparing to reported Q-factors in the literature (e.g., \[23\]).

FIG. S1. Transmission Electron Microscopy Image of an exemplary network.
