Abstract—THz transmissions suffer from pointing errors due to antenna misalignment and incur higher path loss because of molecular absorption at such a high frequency. In this paper, we employ an amplify-and-forward (AF) dual-hop relay to mitigate the effect of pointing errors and extend the range of a wireless backhaul network. We provide statistical analysis on the performance of the considered system by deriving analytical expressions for the outage probability, average bit-error-rate (BER), and a lower bound expressions for the outage probability, average bit-error-rate the performance of the considered system by deriving analytical expressions for the outage probability, average bit-error-rate (BER), and a lower bound expressions for the outage probability, average bit-error-rate (BER), and a lower bound.

Index Terms—Amplify-and-forward, Backhaul, Bit-error-rate, Diversity order, Ergodic capacity, Signal-to-noise ratio, TeraHertz.

I. INTRODUCTION

There is currently a lot of research work in both academia, and the industry alike in 5G communication technology that uses millimeter-wave (mmWave) frequency bands up to 60 GHz [1]. Apart from conventional cellular communication, diverse applications in the field of wireless cognition, autonomous driving, positioning, augmented reality, etc., will need higher performance than what mmWave bands can offer [2]. In cellular networks and Internet of Things (IoT) applications, the increase in the number of wireless devices has put a huge strain on existing communication technologies. There is thus a need to explore high-frequency bands, such as those in the Terahertz (0.3-3 THz) and sub-Terahertz (60-300 GHz) range. These bands offer more flexibility and are also economically more viable than the conventional backhaul infrastructures in difficult terrains and hence will be the frequency bands of choice for future backhaul networks [3].

However, the THz band has its challenges and limitations. While the high-frequency bandwidths can offer much higher rates and lower latency than even 5G systems, signals in these bands suffer from severe path loss and atmospheric attenuation [4]-[7]. The path loss is higher because of molecular absorption at such small wavelengths. The authors in [4] have developed an experimental characterization of the THz channel whereas in [5], the authors have examined the effect of scattering and absorption losses in the THz band. There is also considerable loss due to antenna misalignment and radio frequency (RF) hardware issues [8], [9]. Hence the physical range of these systems is minimal. Cooperative communication systems are a practical solution to mitigate the impact of path loss and channel conditions [10]. This motivates us to analyze and explore the performance of such relayed THz systems for the dual-hop scenario.

Related Works: The dual-hop relaying for THz and heterogeneous networks has also been discussed in the literature [11]-[16]. In [11], the authors derived a closed-form solution for hybrid precoding in two-way relayed THz multiple input multiple output (MIMO) wireless systems. The sum capacity and energy efficiency of the proposed system were better than existing solutions for the THz MIMO relay system. The authors in [12] investigate the performance of a cooperative relay transmission system for nano-sensor networks in the THz band using both Amplify-and-Forward (AF) and Decode-and-Forward (DF) relaying assuming a Line of Sight (LOS) channel in the THz band. Similarly, in [13], the authors focused on the application of THz communication in vivo nano-devices. In [14], the authors analyze the outage performance of a dual-hop THz wireless system considering the effect of antenna misalignment error. [15], considers a mixed dual-hop case, with an RF and THz link with misalignment error. The small-scale multi-path fading is considered to be a generalized $\alpha-\mu$ distribution, which includes Weibull, negative exponential, Nakagami-m, and hence Rayleigh and Rician fading distributions. In [16], the authors analyzed the performance of a THz-RF wireless link over an $\alpha-\mu$ fading channel. They derived the closed-form expressions for various performance metrics such as outage probability, average BER, ergodic capacity, etc. To the best of the author’s knowledge, a dual-hop cooperative communication system operating purely with THz links has not been explored or analyzed in the literature and is highly desirable for the upcoming generations of wireless communications.

In this paper, we present the performance analysis of a dual-hop THz-THz wireless system by considering generalized $\alpha-\mu$
fading combined with misalignment errors using AF protocol. First, we present the probability density function (PDF) and cumulative distribution function (CDF) for the dual-hop AF relay system. Further, using the PDF and CDF, we derive exact closed-form expressions of outage probability, average BER, average SNR, and a lower bound on the ergodic capacity of the relayed system. We also confirm our results using the diversity order analysis. Finally, we validate our derived analysis using Monte-Carlo simulations.

Notations: Some notations that are used in the paper are as follows. $\Gamma(\cdot)$, $\Gamma(\cdot, \cdot)$, and $\psi(\cdot)$ denote the Gamma, upper incomplete Gamma and digamma function, respectively. $B_2(\cdot, \cdot)$ denotes the Beta function and $2F_1(\cdot, \cdot; \cdot)$ denotes the Gaussian Hypergeometric function. Finally, $G_{p,q}^{m,n}\left( \frac{\alpha_1, \ldots, \alpha_n}{b_1, \ldots, b_q} \right)$ denotes the Meijer’s G function.

II. System Model

We consider a dual-hop relay system in which the information is transmitted from source (S) to destination (D) via a relay (R) node with AF protocol. The considered system may be well suited for backhaul transmissions in small-cell networks, cell-free wireless networks, etc., to transmit the information to the central processing unit (CPU). The THz band facilitates the communication on both the hops, i.e., between source to relay and relay to destination. We assume that direct transmission from the source to the relay is not possible due to obstacles present in between. We consider generalized i.i.d. $\alpha$-$\mu$ short-term fading along with zero boresight pointing errors. The received signal at the relay or destination can be represented as

$$y_i = h_{i}h_{pf}x_i + w_i,$$

where $i = \{1, 2\}$ denote the first hop (S-R) and second hop (R-D), respectively.

$x_i$ and $w_i$ are the transmitted signal and additive white Gaussian noise at the $i$th link. $h_i$ is the THz channel total path-gain and is given as

$$h_i = \frac{c\sqrt{G_s G_r}}{4\pi f d_i} \exp \left( -\frac{1}{2}k(f, T, \psi, p)d_i \right)$$

where $k$ is the absorption coefficient and can be calculated as given in $[17]$. The random variable $h_{pf}$ combines the effect of fading and antenna misalignment having PDF $[15]$,

$$f_{h_{pf}}(x) = \phi S_0^{-\phi} \frac{\mu^\phi}{\Omega^\phi \Gamma(\mu)} x^{\phi - 1} \Gamma \left( \frac{\alpha \mu - \phi}{\alpha} , \frac{\mu}{\Omega} S_0^{-\alpha} \right)$$

$$f_{h_{pf}}(x) = A x^{\phi - 1} \Gamma (B, C x^\alpha)$$

where $\alpha$, $\mu$ are the fading parameters and $A = \phi S_0^{-\phi} \mu^\phi \frac{\mu}{\Omega^\phi \Gamma(\mu)}$, $B = 2^{\alpha - \phi} \frac{\phi}{\mu}$, and $C = \frac{\mu^\phi}{\Omega^\phi S_0^{-\alpha}}$. Here, $\Omega$ is the $\alpha$ root mean value of the fading channel envelope and $\phi$, $S_0$ are the pointing error parameters as presented in $[18]$.

Using $[3]$, the PDF of instantaneous SNR of the THz link can be represented as,

$$f_{\gamma_i}(\gamma) = \frac{A}{2\sqrt{\gamma_0}} \left( \frac{\gamma}{\gamma_0} \right)^{\phi - 1} \Gamma (B, C \left( \frac{\gamma}{\gamma_0} \right)^\alpha)$$

and the CDF is given as $[16]$.

$$F_{\gamma_i}(\gamma) = \frac{AC^\phi}{\phi} \left[ \Gamma \left( \mu \left( \frac{\gamma}{\gamma_0} \right)^\alpha \right) + C^\phi \left( \frac{\gamma}{\gamma_0} \right)^\phi \times \Gamma \left( B, C \left( \frac{\gamma}{\gamma_0} \right)^\alpha \right) \right]$$

The instantaneous SNR of the THz link is denoted by $\gamma = \gamma_0 |h_{pf}|^2$ where $\gamma_0 = P|h_{i}|^2/\sigma_w^2$ is the SNR term without channel fading for the THz link with transmit power $P$. The end-to-end SNR for a CSI assisted AF relay is given by $[19]$

$$\gamma = \frac{\gamma_1 \gamma_2}{\gamma_1 + \gamma_2 + 1}$$

III. Performance Analysis

In this section, we will derive the analytical expressions of outage probability, average BER, ergodic capacity, and average SNR for the dual-hop relaying system. Since the exact analysis of the CSI assisted AF relay demands the use of more complex mathematical functions like Fox’s H and rigorous computations, we use an upper bound for the analysis of the considered system for which the end to end SNR is given by $[20]$

$$\gamma = \min \{\gamma_1, \gamma_2\}$$

The distribution functions are given by

$$F_{\gamma} = F_{\gamma_1} + F_{\gamma_2} - F_{\gamma_1} F_{\gamma_2}$$

$$f_{\gamma} = f_{\gamma_1} + f_{\gamma_2} - f_{\gamma_1} f_{\gamma_2}$$

where $f_{\gamma_1}$, $f_{\gamma_2}$ denote the PDFs of the first and second hops, respectively and $F_{\gamma_1}$, $F_{\gamma_2}$ denote the CDFs of the first and second hops, respectively.

A. Outage Probability

Outage probability is defined as the probability of instantaneous SNR value being less than some threshold value $\gamma_{th}$ such that the system goes into outage i.e., $P_{out} = P(\gamma < \gamma_{th})$.

The outage probability can be evaluated by substituting $\gamma_{th}$ into $[2]$ where $F(\gamma)$ is given in $[6]$.

The diversity order of the relayed system is obtained using the asymptotic analysis in high SNR regime, $[16]$

$$M = \min \left\{ \frac{\alpha \mu \phi}{2}, \frac{\phi}{2} \right\}$$

B. Average BER

The average BER of the presented system is given as $[21]$

$$P_e = \frac{q^p}{2\Gamma(p)} \int_0^\infty \gamma^{p-1} e^{-q\gamma} F_\gamma(\gamma) d\gamma$$

where $p$ and $q$ are modulation parameters.
Lemma 1: if $\phi$ and $S_0$ are the pointing error parameters, and $\alpha, \mu$ are the fading parameters, then average BER of the relay assisted link is given in (12).

Proof: See Appendix A for the proof. ■

It is to be noted that the diversity order for average BER is same as that for the outage probability given in [16].

C. Ergodic Capacity

Using (10) and the identity $\log_2(1+\gamma) \geq \log_2(\gamma)$, we define a lower bound on the ergodic capacity

$$C = \int_0^\infty \log_2(\gamma) f_\gamma(\gamma) d\gamma$$

(14)

Lemma 2: if $\phi$ and $S_0$ are the pointing error parameters, and $\alpha, \mu$ are the fading parameters, then ergodic capacity of the relay assisted link is given as

$$C = \frac{4AC}{\alpha^2} \Gamma(\alpha - \phi) \left[ -\alpha + \phi (\ln \gamma_0 - \ln C + \psi(\mu)) \right]$$

$$\times (\phi - AC \frac{\gamma_0^\alpha}{\alpha^2} \Gamma(\mu)) + \frac{4AC}{\alpha^2} \left[ \alpha \gamma_0^\alpha \ln 2 \right]$$

$$\times \left\{ \gamma_0^{\alpha \phi - \alpha} \Gamma(\mu) + \frac{4AC}{\alpha^2} \Gamma(\alpha - \phi) \right\}$$

$$\times \left\{ \delta_0^{\alpha \phi - \alpha} \Gamma(\mu) + \frac{4AC}{\alpha^2} \Gamma(\alpha - \phi) \right\}$$

$$\times \left\{ \delta_0^{\alpha \phi - \alpha} \Gamma(\mu) + \frac{4AC}{\alpha^2} \Gamma(\alpha - \phi) \right\}$$

(15)

Proof: We substitute (5) in (14), and define

$$\bar{C} = \int_0^\infty \log_2(\gamma) f_\gamma(\gamma) d\gamma$$

(17)
Lemma 3: if \( \phi \) and \( S_0 \) are the pointing error parameters, and \( \alpha, \mu \) are the fading parameters, then the average SNR of the relay assisted link is given as

\[
\begin{align*}
\bar{\gamma} &= \frac{A_{\alpha \mu} C_{\alpha \mu}}{\phi(t + \phi)(2 + \phi)} 2(1 + \phi)(C^2 - \phi(1 + \phi)(2 + \phi)) \\
&+ A_{\phi}\Gamma\left(\frac{2 + \alpha + \phi}{\alpha}\right) \Gamma\left(B + 1\right) + \left(\frac{1}{\alpha} + \phi\right) \Gamma\left(\frac{1}{2} - \frac{1}{\alpha} + \phi\right) \\
&\times \left[2\left(1 - \frac{1}{(1 + \phi)}\right)\left(1 + \phi\right)B_{-1} \left[\frac{1}{\alpha}; \frac{1}{\alpha}, 1 - 2\left(\frac{1}{\alpha} + \phi\right)\right] \\
&- \left(\frac{1}{\alpha}(2\phi + 2)F_2\left(\frac{1}{2} + \phi\right) \frac{2 + \alpha + \phi + \phi}{2 + \alpha + \mu + \phi}; 1, -1\right)\right] \\
&= \frac{\alpha(2 + \phi)}{2} F_2\left(\frac{1}{2} + \phi, \frac{2 + \alpha + \phi + \phi}{2 + \alpha + \mu + \phi}; 1, -1\right).
\end{align*}
\]

(18)

Proof: We substitute (10) in (17), and define \( \sqrt{\gamma/\gamma'_1} = t \) we get the average SNR of the relay assisted link

\[
\bar{\gamma} = \int_0^\infty \gamma' t^{-1} F_2(\gamma) \frac{1}{\phi} + \frac{A_{\phi}}{\mu} \Gamma(\mu) \\
\int_0^\infty t^{2 + \phi} \Gamma(B, Ct) dt - \frac{A_{\phi}}{\mu} \int_0^\infty t^{2 + \phi} \Gamma(B, Ct)^2 dt \\
+ \frac{A_{\phi}}{\mu} \Gamma(\mu) \int_0^\infty t^{2} t^{\phi} \Gamma(B, Ct) \Gamma(\mu, Ct) dt
\]

(19)

The first and the second integral can be solved using the identity \([24, 6.455/1]\). The third integral is solved by applying the integration-by-parts method with \( \Gamma(B, Ct) \) as the first and \( t^{2 + \phi} \Gamma(B, Ct) \) as the second term. We follow a similar procedure to solve the fourth integral. Finally, using the limits of the integrals in the following identity, we get the solution for both the integrals.

\[
\int t^{x-1} \Gamma(a, t) dt = \frac{t^x \Gamma(a, t) - \Gamma(a + x, t)}{x}
\]

(20)

Further, to simplify the expression, we use the following identity to represent hypergeometric functions,

\[
B_z(a, b) = \frac{z^a}{a} \binom{2}{a} (1 - b; a + 1; z)
\]

(21)

By solving the integrals and substituting them into (19), we get the closed form expression for the average SNR as given in (18).

IV. SIMULATION AND NUMERICAL RESULTS

In this section, we validate the derived analytical expressions with the help of Monte-Carlo simulations (averaged over \( 10^7 \) channel realizations) on MATLAB software. We consider an operating frequency of 275 GHz, and transmit and receive antenna gains as \( 45 \) dB. Using the parameters given in (17), the path-loss is calculated for the THz link. For all simulations, we consider an \( \alpha-\mu \) fading channel model. To see the impact of the diversity order from Eq. (11), we vary the values of \( \alpha, \mu, \) and \( \phi. \) The value of fading parameters \( \alpha \) and \( \mu \) are taken in the range of \( 1-3, \) since these values cover most of the distributions given by the generalized \( \alpha-\mu \) model. Pointing error parameters \( \phi \) and \( S_0 \) are calculated using the values provided in (18). We take the noise PSD for THz to be \( -174 \) dBm and the channel bandwidth equal to 10 GHz (25).

In Fig. 1, we illustrate the outage probability performance of the relayed system for an SNR threshold of 4 dB. It is evident from the figure that the outage performance decreases with an increase in parameter \( \phi, \) for the same fading parameter values. We can observe the impact of the fading and pointing error parameters on the outage performance. The diversity order depends on the pointing error parameter for different values of fading parameters \( \alpha \) and \( \mu \) when \( \phi = 6.7, \) which is verified by the change in slope of the plots. In Fig. 2, we present the average BER performance of the system. Similar to the outage probability, when the parameter \( \phi \) increases, the BER decreases. When the values of the channel parameters
\( \alpha = 1 \) and \( \mu = 1.5 \), the diversity order remains unchanged, and the slope of the BER curve does not change. However, when \( \alpha \) and \( \mu \) are increased to 2 and 2.5 respectively, the diversity order now becomes dependent on \( \phi \) and the change in slope of the BER curves confirms the correctness of the expressions.

In Fig. 2, we demonstrate the average SNR performance of the relaying system. The SNR is plotted against the pointing error parameter \( \phi \) for different transmitted power, and \( \alpha = 1 \) and \( \mu = 1.5 \). As \( \phi \) is increased, the average SNR first increases and then saturates, which implies that there is not much improvement in the link performance beyond a certain value of \( \phi \). We can see a significant increase in the SNR as the transmitted power is increased. In Fig. 2, we analyze the ergodic capacity of the dual-hop system. As expected, as the link distance increases, the capacity decreases. When the transmit power is increased from 0 dBm to 30 dBm, the total capacity increases by nearly 100 Gbps. Fig. 2 also provides valuable insights on the range of the system. The capacity is high (100 Gbps) even when the link distance is 40 m, for a transmit power of 30 dBm. The placement and power of the THz relay being used for the backhaul operation can be varied based on the capacity requirements. All four plots also validate our analytical expressions due to excellent agreement between simulations and values derived from the analysis presented.

**V. CONCLUSION AND FUTURE WORK**

The performance of a dual-hop THz-THz wireless system is investigated in this paper. We have considered a generalized i.i.d \( \alpha-\mu \) fading channel model combined with the statistical pointing errors. We obtained closed-form expressions for the PDF and CDF of the end-to-end SNR for the dual-hop THz relay systems. We have derived exact closed-form expressions for the outage probability, average BER, average SNR, and a lower bound on the ergodic capacity of the relay-assisted system. We verified the outage probability and average BER expressions with the help of the diversity order. The derived results were confirmed with the Monte-Carlo simulations under different channel conditions and for different parameter values. Finally, we can see that data rates up to several Gbps can be achieved with the THz transmissions, which may fulfill the demands of the future generation wireless systems. The work presented in this paper can be further explored by an exact analysis of the performance of CSI assisted AF relay or a multi-hop THz system.

**APPENDIX A: PROOF OF LEMMA 1**

Using (9) in (13), we define the average BER as
\[
\bar{P}_e = \bar{P}_{e_{t_1}} + \bar{P}_{e_{t_2}},
\]
where
\[
\bar{P}_{e_{t_1}} = \frac{C^{-\alpha} \gamma_{\gamma_0}^{\frac{2}{\alpha}}}{2 \sqrt{2 \pi} \sigma^2(\phi)} \left[ \int_0^{\infty} \Gamma(\mu) e^{-\gamma(2x+1)} \gamma^{2x-3} d\gamma \right] + C^{-\alpha} \gamma_{\gamma_0}^{\frac{2}{\alpha}} \left[ \int_0^{\infty} \Gamma(\mu, C(\gamma_0)^{\frac{2}{\alpha}}) e^{-\gamma(2x+1)} \gamma^{2x-3} d\gamma \right] - \int_0^{\infty} \Gamma(\mu, C(\gamma_0)^{\frac{2}{\alpha}}) e^{-\gamma(2x+1)} \gamma^{2x-3} d\gamma \right] (22)
\]
The first integral is straightforward and can be solved easily. For the second integral we use the approximation for \( \Gamma(\mu, B\gamma_0^{\frac{2}{\alpha}} \gamma^{\frac{2}{\alpha}}) \) using \( \Gamma(a, x) \approx e^{-x} x^{a-1} \). Further, we apply the identity of the product of two Meijer’s G function \[23\] to get the solution. For the third integral, we use the series expansion of \( \Gamma(\mu, B\gamma_0^{\frac{2}{\alpha}} \gamma^{\frac{2}{\alpha}}) \) using \( \Gamma(a, bx) = (a - 1) e^{(-bx)} \sum_{k=0}^{\infty} \frac{(-bx)^k}{k!} \) and apply the identity \[23\]. We define
\[
\bar{P}_{e_{t_2}} = \frac{C^{-\alpha} \gamma_{\gamma_0}^{\frac{2}{\alpha}}}{2 \sqrt{2 \pi} \sigma^2(\phi)} \left[ \int_0^{\infty} \Gamma(\mu) e^{-\gamma(2x+1)} \gamma^{2x-3} d\gamma \right] + C^{-\alpha} \gamma_{\gamma_0}^{\frac{2}{\alpha}} \left[ \int_0^{\infty} \Gamma(\mu, C(\gamma_0)^{\frac{2}{\alpha}}) e^{-\gamma(2x+1)} \gamma^{2x-3} d\gamma \right] - \int_0^{\infty} \Gamma(\mu, C(\gamma_0)^{\frac{2}{\alpha}}) e^{-\gamma(2x+1)} \gamma^{2x-3} d\gamma \right] (22)
\]
which can be
rewritten as

\[ P_{\text{el}}(\frac{A}{\sqrt{8\pi n_0^2}}) = \sum_{p=0}^{\infty} \left[ C_{\frac{\gamma}{\gamma_0}} \frac{2}{p} \right] e^{-\gamma} \int_{0}^{\infty} (\Gamma(b_1, b_2, \gamma)) e^{-\gamma(2b_1+1)} \gamma^{2b_1-1} d\gamma \]

Following the similar procedure applied for (22), we solve (23).

The first integral is straightforward and can be solved easily. For the second integral, we use approximation for (22) and apply the identity [23]. Likewise, following the similar procedure for subsequent integrals and upon adding the solutions we get (12).
