ABSTRACT. We consider continuous-time survival or more general event-history settings, where the aim is to infer the causal effect of a time-dependent treatment process. This is formalised as the effect on the outcome event of a (possibly hypothetical) intervention on the intensity of the treatment process, i.e. a stochastic intervention. To establish whether valid inference about the interventional situation can be drawn from typical observational, i.e. non-experimental, data we propose graphical rules indicating whether the observed information is sufficient to identify the desired causal effect by suitable re-weighting. In analogy to the well-known causal directed acyclic graphs, the corresponding dynamic graphs combine causal semantics with local independence models for multivariate counting processes. Importantly, we highlight that causal inference from censored data requires structural assumptions on the censoring process beyond the usual independent censoring assumption, which can be represented and verified graphically. Our results establish general non-parametric identifiability and do not rely on particular survival models. We illustrate our proposal with a data example on HPV-testing for cervical cancer screening, where the desired effect is estimated by re-weighted cumulative incidence curves.

Key words and phrases. Causal inference; Cervical cancer; Independent censoring; Local independence models; Survival analysis; Re-weighting.
1. Introduction

Survival analysis is a fundamental field of biostatistics. In medical journals, statistical tools like Kaplan-Meier plots and Cox regression are very prominent, and the original papers for these two methods are among the most cited in all scientific literature. The typical aim of many medical or epidemiologicial studies is to investigate, for instance, how to delay the event of death, progression of disease or other untoward occurrences. More generally, interest in modelling events in time is fundamental to various areas of application. There are many complex aspects to survival or event-history analyses in general, and numerous statistical methods to deal with them. In the present article, we focus on the question: under what assumptions and how do we use event-history data to describe a situation where a time-dependent treatment or exposure process is changed, e.g. by some intervention or manipulation. In accordance with a wide literature, we consider this as a question of causal inference (Dawid and Didelez, 2010; Pearl, 2009; Peters et al., 2016; Robins, 1986; Rubin, 1974; Spirtes et al., 2000).

Specifically, we are concerned with situations where we wish to evaluate the effect for a, possibly hypothetical, situation where a treatment or exposure process is manipulated so that its intensity process changes. This is relevant, for example, when the research question is to compare early treatment initiation versus later treatment initiation, or to compare higher treatment frequency, say, of radiation therapy, versus lower treatment frequency (Ryalen et al., 2018a).

In a longitudinal context, popular models for the causal effects of time-dependent treatments are marginal structural models (MSMs) (Hernán et al., 2000; Robins et al., 2000). Most of the existing MSM approaches are based on discrete-time models, which is often appropriate or a good approximation. Here, in line with much of the survival analysis literature, we focus on continuous-time MSMs adopting the framework of counting processes (Aalen et al., 2008; Andersen et al., 1993; Røysland, 2011).

A key requirement, before carrying out any data analysis, is to establish whether valid inference about the interventional situation can, at least in principle, be drawn from the available data; latent processes may pose an obstacle, even in randomised studies, especially when they induce unobserved time-dependent confounding (Robins, 1986). Hence, non-parametric identification of the target of inference should be ensured (Manski, 2003; Shpitser and Pearl, 2006). In the field of causal inference, formulating and checking assumption for identification has benefited hugely from graphical representations, in particular from causal DAGs (Dawid, 2002; Pearl, 1995; Robins, 2001), where a complete characterisation of identifiability via graphical
Graphical criteria for the identification of marginal causal effects in continuous-time survival and event-history analyses

Criteria based on $d$-separations is available (Shpitser and Pearl, 2006, 2008). However, neither causal DAGs nor these criteria can easily be transferred to continuous-time situations modelled with stochastic processes, which may exhibit feedback and censoring (Aalen et al., 2012). To remedy this shortcoming, so-called local independence graphs and the corresponding notion of $\delta$-separation have been suggested as alternative representations of (in)dependencies between processes (Didelez, 2006, 2008); so-far, these have lacked an explicit causal semantic despite being used in causal contexts (Mogensen and Hansen, 2020; Røysland, 2012). The central contribution of the present paper is, therefore, to propose the concept of causally valid local independence graphs, and to provide a graphical criterion for the identification of marginal causal effects using continuous-time MSMs for time-to-event outcomes. While the conditions for identification essentially demand the absence of unobserved (time-dependent) confounding, censoring presents an added complication as it further limits, and possibly biases, the information provided by the observable data. As we show, censoring must not only be independent in a probabilistic sense (Andersen, 2005) but also in a causal sense (to be formalised later), i.e. it must allow inference for a situation where censoring is prevented (Hernán and Robins, 2020). Our results on graphical criteria for identification thus encompass issues of time-dependent confounding as well as right-censoring. Once it has been established that the desired causal effect parameter is identifiable, the continuous-time MSM can be fitted by a weighting method (Ryalen et al., 2019). The required continuous-time weights are similar to inverse-probability of treatment (IPTW) and censoring weighting (IPCW), known from discrete-time MSMs. In fact, the latter can be considered as an approximation to the continuous-time weights. The weighting approach is based on a change of measure technique known from stochastic calculus and financial modelling (Røysland, 2011). We conclude by an illustration of our approach with the example of HPV-testing for cervical cancer screening; this is a more advanced analysis, and provides a formal justification for the analysis in Nygård et al. (2014).

Set-up and notation

We consider the following data situation: A collection of independent individuals, say, patients, are observed over time $t \in [0, T]$, where $T$ is the end of follow-up, and $t = 0$ denotes baseline. There may be baseline measurements, but events of interest occur over time: the outcome event(s), e.g. survival; a treatment event, e.g. start or switch of treatment; and possibly other events such as the occurrences of side-effects etc. A special event is that of censoring. All these events are represented by counting processes, where $N_i^j$ indicates how often an event...
of type $i$ has occurred by time $t$. Where relevant, we will specifically denote by $N^y$ and $N^x$ (omitting the subscript $t$) the outcome and treatment processes, respectively. The process $N^c$ denotes the counting process for censoring; sometimes we refer to $C$ as the jumping time of $N^c$. We assume throughout that the compensators of the considered counting processes are absolutely continuous, which implies that the counting processes jump at different times (with probability 1) and together form a multivariate counting process (Andersen et al., 1993). When referring to the intensity of a counting process $N$ we are tacitly referring to a version of the predictable intensity of $N$. We will repeatedly use the fact that these intensities, combined with the distribution over the baseline variables, uniquely determine the distribution $P$ over the considered variables and processes (Jacod and Shiryaev, 2003, Theorem III 1.26).

A continuous-time MSM, as introduced formally in Section 6, models the effect of a strategy for generating $N^x$ on some aspect of $N^y$. Let $P, \lambda$ denote the observational distribution and intensities, then we use $\tilde{P}, \tilde{\lambda}$ for quantities under an intervention on $N^x$ that enforces that strategy. For example, $\tilde{S}(t) = \tilde{P}(N^y_t = 0)$ might denote the survival probability under a strategy such as ‘early treatment initiation’ specified by a given intensity $\tilde{\lambda}^x$ for $N^x$, where $\tilde{\lambda}^x$ is enforced by the intervention. In order to be able to evaluate such effects from observational, i.e. non-interventional, data generated from $P$, time-varying confounding needs to be addressed. We will formulate criteria characterising which information can be ignored without introducing bias. In order to address questions relating to unobservable variables or events, we will ‘move’ between different sets of information: $V$ denotes the set of all variables and processes deemed ‘relevant’ to a system, including the censoring process; this includes baseline variables $X \in B$, as well as counting processes $N \in N$. Here, ‘relevant’ refers to the requirement that the resulting model is causally valid as formalised in Section 3 below. Throughout, we are concerned with interventions on processes, not in baseline variables; the latter are included to define subgroups of interest, or because they may be needed to adjust for baseline confounding. Note that an intervention on a process does not affect the distribution of baseline variables as a cause has to come before the effect in time.

It may not be possible to observe the complete set of variables and processes, or we may not be interested in all of these. Thus, $V_0 = B_0 \cup N_0$ denotes the subset of baseline variables and processes that we focus on or can observe; these exclude $N^c_i$ as inference typically aims at an uncensored situation (to be formalised). We will sometimes use the notation $\dot{U}$ for the union of pairwise disjoint sets. Where appropriate, we explicitly refer to sets of unobserved variables or processes by $U$, and to sets of observed processes that are not of primary interest.
as $\mathcal{L}$. Thus, the analysis is marginal over $\mathcal{U}$ and the MSM is further marginal over $\mathcal{L}$. Note also that often we will not distinguish between baseline variables and processes, as a variable can be understood as a constant process on $t > 0$. We will highlight where it is important to distinguish baseline variables from processes.

Throughout, we use $\mathcal{F}$ (or $\mathcal{F}_t$) for a $\sigma$-algebra (or filtration) on the full set of information generated by $\mathcal{V}$. To improve readability, we will prefer the notation $\mathcal{F}$ for the filtration (dropping the subscript $t$) unless time needs to be explicitly referenced. When a $\sigma$-algebra (filtration) is generated by a subset $A \subset \mathcal{V}$ of processes we write $\mathcal{F}^A (\mathcal{F}^A_t)$, where we also use $\mathcal{F}^{a,b}$ instead of $\mathcal{F}^{(a,b)}$. Here, we associate processes/variables with their indices so that the filtration generated by $N^a$ is denoted by $\mathcal{F}^a$ and the filtration generated by $N^a$ and $N^b$ with $\mathcal{F}^{a,b}$, etc. Finally, $P|_{\mathcal{F}^A}$ denotes the restriction of a probability measure to the reduced set of information $\mathcal{F}^A$.

2. Graphical Local Independence Models

Graphical local independence models (or, local independence graphs) have been suggested and investigated by Aalen (1987); Didelez (2007, 2008); Mogensen and Hansen (2020); Schweder (1970). They can be seen as stochastic processes’ counterpart to directed acyclic graph models or Bayesian networks (Lauritzen, 1996). They graphically encode the probabilistic (in)dependence structure between processes. Unlike Bayesian networks, which represent conditional independencies between variables, the independencies between processes are in terms of local independencies. Informally this means that, at any time, the presence of one process does not depend on the past of another process given some other information on the past; hence this is an asymmetric notion of independence (Didelez, 2006). In the graph below, for instance, we represent that the process $N^a$ is locally independent of the process $N^b$ but not vice versa:

\[ N^a \rightarrow \rightarrow N^b. \]

In this section, we give basic background information on local independence graphs before we formalise the corresponding causal semantics in Section 3. For formal details on local independence and its graphical properties, see (Didelez, 2006, 2008).

2.1. Intensities and local independence. A key concept is that of the intensity of a counting process $N_t$, which throughout we assume to exist for all counting processes. It establishes the dependence between the process’ present, or short-term prediction, and ‘past information’.
Here, we review the concept briefly; a precise mathematical treatment requires tools from martingale theory, see Aalen et al. (2008) or Jacod and Shiryaev (2003).

Let \( \mathcal{F} \) be a filtration generated by a set of variables and processes, e.g. those in a set \( \mathcal{V} \) including \( N \), then the \( \mathcal{F} \)-intensity of \( N \) satisfies

\[
E(dN_t|\mathcal{F}_{t-}) = \lambda_t dt.
\]

Crucially, the intensity depends on what past information we include. For instance, the \( \mathcal{F} \)-intensity and the \( \mathcal{G} \)-intensity, for a reduced information \( \mathcal{G}_t \subset \mathcal{F}_t \), of the same process \( N \) are not necessarily identical; the latter can be obtained through the Innovation Theorem (Andersen et al., 1993, II.4.2).

However, when the intensity for a reduced set of past information does remain the same, we speak of a local independence. Specifically, consider \( N^a, N^b \in \mathcal{N} \). Then we say that \( N^a \) is locally independent of \( N^b \) given \( \mathcal{V}\setminus\{b\} \) if the \( \mathcal{F}^{\mathcal{V}} \)-intensity of \( N^a \) is indistinguishable from its \( \mathcal{F}^{\mathcal{V}\setminus\{b\}} \)-intensity (where \( b \) can also index a baseline variable). Thus, local independence formalises the intuitive notion that the short-term prediction of \( N^a \) is unchanged when removing information on the past of \( N^b \) as long as past information generated by variables and processes in \( \mathcal{V}\setminus\{b\} \), including its own past, is given. To make this last point explicit, we always include the process \( N^a \) itself in the conditioning set (note, Didelez (2008) uses the same concept but slightly different notation). Alternatively, we can define local independence using martingales: \( N^a \) is locally independent of \( N^b \) given \( \mathcal{V}\setminus\{b\} \), if \( N^a_t - \int_0^t \bar{\lambda}_s ds \) is a local martingale with respect to \( \mathcal{F}^{\mathcal{V}} \) when \( \bar{\lambda} \) is the \( \mathcal{F}^{\mathcal{V}\setminus\{b\}} \)-intensity of \( N^a \). We write local independence as \( N^b \not\rightarrow N^a | \mathcal{V}\setminus\{b\} \) or \( b \not\rightarrow a | \mathcal{V}\setminus\{b\} \) for short.

As a convention, we always include a process’ own history in the filtrations for its different intensities. A detailed treatment of local independence can be found in Aalen (1987) and Didelez (2008) with further generalisations by Mogensen and Hansen (2020). Some important properties of local independence are (i) that it is asymmetric and (ii) it is relative to the set of given information \( \mathcal{V} \). If \( N^a \) is locally independent of \( N^b \) given \( \mathcal{V}\setminus\{b\} \) then this does not necessarily imply the converse, nor does it imply local independence given a subset \( \mathcal{V}_0\setminus\{b\} \), \( \mathcal{V}_0 \subset \mathcal{V} \).

2.2. Local independence graphs and models. We now turn to the graphical representation of local independence structures. A graph \( G = (\mathcal{V}, \mathcal{E}) \) is given by a set of vertices (or nodes) \( \mathcal{V} \) and edges \( \mathcal{E} \); the nodes represent variables or processes; there can be up to two edges between nodes representing dynamic relations. The induced subgraph \( G_A, A \subset \mathcal{V} \), has nodes \( \mathcal{V} \cap A \)
GRAPhICAL CRITERIA FOR THE IDENTIFICATION OF MARGINAL CAUSAL EFFECTS IN CONTINUOUS-TIME SURVIVAL AND EVENT-HISTORY ANALYSES

and edges $E \cap (A \times A)$; a subgraph $G'_A$ on $A$ is given if the edges are a subset of those of the induced subgraph. Any node $b \in V \setminus \{a\}$ with an edge $b \rightarrow a$ is called a parent of $a$, while $a$ is a child of $b$; graphical ancestors or descendants are defined analogously in terms of sequences of directed edges. In order to represent local independence structures, a graph should satisfy the following properties:

- the node set, $V = B \cup N$, consists of two types, representing either baseline variables or processes;
- all edges are directed;
- between two nodes in $N$ there may be up to two edges, one in each direction;
- between two nodes in $B$ there can only be up to one edge;
- there are no edges pointing from a node in $N$ to a node in $B$;
- on the subset $B$ of baseline variables the graph is a directed acyclic graph (DAG).

We call a graph with the above properties local independence graph.

A graphical local independence model, $(P, F, G)$, combines the above graph with a class $\mathcal{P}$ of distributions by demanding that when there is no edge pointing from a given node to a given process then the corresponding local independence must hold for every $P \in \mathcal{P}$. Among the baseline variables (i.e. for their marginal joint marginal distribution) we require the usual directed Markov properties of conditional independence graphs to hold (Lauritzen, 1996). Formally, let $G$ be a local independence graph satisfying the above properties. The corresponding graphical local independence model is a class of joint distributions $P = \mathcal{P}(G)$ for all possible outcomes or trajectories of the nodes in $V$ such that, under any $P \in \mathcal{P}(G)$

- the $F$-intensity $[1]$ is well defined for each counting process in $N$;
- when $(b \rightarrow a) \notin E$, and $a \in N$, then $N^a$ is locally independent of $N^b$ given $N^{V \setminus \{b\}}$;
- $P|_{F^B}$ satisfies the conditional independencies given by the directed Markov properties of the induced subgraph $G_B$.

Under regularity conditions the above definition implies that every counting process $N^a$ is locally independent of its non-parents, conditionally on its closure, defined as $\text{cl}(a) = \{a\} \cup \text{pa}(a)$. This means that the $F$-intensity of $N^a$ is indistinguishable from its $F^{\text{cl}(a)}$-intensity. In the example $[2]$ below we find that $N^1$ is locally independent of $N^2$ given $N^{1,3}$, and that there
are no other local independencies implied by the graph:

\[ N_1 \downarrow \downarrow \downarrow \downarrow \downarrow N_2 \rightarrow N_3 \leftarrow N_3 \]

A further example combining baseline variables and processes is given in Appendix A.

2.3. $\delta$-separation. In order to use graphical local independence models for causal reasoning, and especially to assess identification of causal parameters, we need to be able to read off independencies retained or dependencies introduced when marginalising over possibly unobservable / latent variables or processes, e.g. to check if these unobservables could induce confounding bias. For instance in the above example graph (2), if $N_3$ were unobservable it could induce a (marginal) local dependence of $N_1$ on $N_2$. This type of property can be read off from a local independence graph by means of $\delta$-separation (Didelez, 2006, 2008), in analogy to $d$-separation for DAGs. Due to the asymmetric nature of local independence, $\delta$-separation must also be asymmetric and is therefore different from $d$-separation.

Before formally defining $\delta$-separation, we require the notions of ‘blocked trail’ and ‘allowed trail’. A trail is a subgraph of $G$ formed by unique vertices $\{v_0, \ldots, v_m\}$ and edges $\{e_1, \ldots, e_m\}$ such that either $e_j = v_{j-1} \rightarrow v_j$ or $e_j = v_{j-1} \leftarrow v_j \in \mathcal{E}$ for every $j = 1, \ldots, m$. The trail is said to start in $v_0$ and end in $v_m$. As there can be multiple edges between nodes, there can be different trails on the same set of nodes. A trail is said to be blocked by a set of vertices $C \subset \mathcal{V}$ if either (i) $C$ contains a vertex $v_j$, $j \in \{2, \ldots, m - 1\}$, on the trail such that $e_j = v_j \rightarrow v_{j+1}$ or $e_{j-1} = v_{j-1} \leftarrow v_j$ on the trail (i.e. $v_j$ is a non-collider), or (ii) the trail contains the edges $v_{j-1} \rightarrow v_j \leftarrow v_{j+1}$ such that $C$ contains neither $v_j$ nor any of its descendants. Otherwise, the trail is said to be open relative to $C$. An allowed trail from a node $v_0$ to a node $v_m$ in $\mathcal{N}$ is a trail ending with a directed edge into the node $v_m$, i.e. $e_m = v_{m-1} \rightarrow v_m$.

In DAGs, for disjoint sets of nodes $A, B, C$, we say $A$ and $B$ are $d$-separated by $C$, if every path between $A$ and $B$ is blocked by $C$; this separation is symmetric in $A$ and $B$. For distributions that satisfy the Markov properties of a DAG, every $d$-separation entails the corresponding conditional independence, i.e. $X_A \perp \perp X_B \mid X_C$ (Lauritzen, 1996; Pearl, 2009, Theorem 1.2.4). In a graphical local independence model, this is still the case for baseline variables $A, B, C \subset \mathcal{B}$, but in addition we use $\delta$-separation to read off local independencies relating to processes as follows (Didelez, 2006, 2008).
Definition 1. Let $a \in \mathcal{N}$ and $B, C \subset \mathcal{V}$ be disjoint subsets of vertices in a local independence graph $G$. Then $B$ is $\delta$-separated from $a$ by $C \cup \{a\}$ if every allowed trail from any $b \in B$ to $a$ is blocked by $C$. For a subset $A \subset \mathcal{N}$, $B$ is $\delta$-separated from $A$ by $A \cup C$ if every allowed trail from any $b \in B$ to any $a \in A$ is blocked by $(A \cup C) \setminus \{a\}$. We then write $B \not\rightarrow_G A \mid A \cup C$.

The role of $\delta$-separation lies in guaranteeing (under regularity conditions) a corresponding local independence in the model (Didelez, 2008, Theorem 1 and 3.4): whenever $B \not\rightarrow_G A \mid A \cup C$ then the sub-process $A$ is locally independent of the processes (or variables) in $B$, given $A \cup C$. As $A \cup B \cup C$ does not need to equal $\mathcal{V}$, $\delta$-separation allows us to infer marginal local independencies in subsets of the systems.

Note that the ‘blocking of allowed trails’ condition has an equivalent ‘moral graph’ condition which allows to check $\delta$-separation on an undirected graph (Lauritzen, 1996); this and much additional information on $\delta$-separation can be found in Didelez (2006).

Remark 1. The definition of local independence graph and $\delta$-separation takes as implicit that every process always depends on its own past so that we do not make use of any self-loops and always condition on a process’ own past. Mogensen and Hansen (2020) make such a distinction; moreover the authors generalise their treatment to dependencies due to latent processes shown graphically as bi-directed edges and self-loops. The corresponding notion of separation is called $\mu$-separation. See Appendix A for further examples.

Remark 2. The above notion of local independence graph ensures that whenever there is a $\delta$-separation in the graph then there is a local independence in the model $\mathcal{P}(G)$. If the converse holds, i.e. all local independencies that hold for every distribution under a probabilistic model $\mathcal{P}$ can be read off from the graph $G$ via $\delta$-separation, then we say that the model is faithful to the graph (Meek, 1995), and the graph corresponding to $\mathcal{P}$ is then unique. Faithfulness is especially relevant in the context of causal discovery (Mogensen et al., 2018). For our following results, here, we do not require faithfulness; nevertheless, in slight abuse of terminology, we will simply say ‘the local independence graph’ when we mean the whole local independence model.

3. Causal Validity of Local Independence Models

Graphical local independence models describe the probabilistic dynamic dependence structure of a multivariate counting process (possibly including baseline variables). We now wish to combine this with causal semantics; for instance, we may have the aim to evaluate whether
a treatment should be initiated earlier rather than later. To this end, we need to be explicit about assumptions that link the probabilistic structure with hypothetical interventions under which the data generating process is modified, reflecting e.g. the situation of earlier treatment initiation. We proceed in analogy to causal DAG models, which reflect causal structures by demanding that the model obeys the ‘manipulation theorem’ or ‘truncation formula’ ([Didelez, 2018](#) [Pearl, 2009](#) [Spirtes et al., 2000](#)). In section 3.2 we propose an analogous notion for local independence graphs.

### 3.1. Local characteristics.

Let \( \mathcal{P}(G) \) be a local independence model on a set of counting processes and baseline variables \( \mathcal{V} = \mathcal{N} \cup \mathcal{B} \), with \( n = |\mathcal{V}| \). It is a consequence of Jacod’s formula, see [Jacod (1975)](#), that there exist functionals \( Z_1, \ldots, Z_n \), such that the joint density of each \( P \in \mathcal{P} \), restricted to the possible events that could occur before \( t \), is uniquely determined and given by the product

\[
\prod_{i=1}^{n} Z^i(\mu^i, t),
\]

where \( \mu^1, \ldots, \mu^n \) are the local characteristics. The factors in (3) corresponding to counting processes \( i \in \mathcal{N} \) can be computed from the \( \mathcal{F} \)-intensities \( \lambda^i \) and the previous jumps. We have that

\[
Z^i(\lambda^i, t) := \prod_{s_i \leq t} \lambda^i_{s_i} \exp \left( - \int_{0}^{t} \lambda^i_s ds \right),
\]

where \( s_i \) denotes the jump times of the counting process \( N^i \).

The graphical structure is reflected in the fact that, as explained earlier, the above \( \mathcal{F} \)-intensities \( \lambda^i \) are indistinguishable from the \( \mathcal{F}^{cl(i)} \)-intensities, i.e. those generated by the past on the graphical parent-nodes of a process and its own past. Additionally, when \( i \in \mathcal{B} \), the local characteristics are not functions of time and are given by the conditional probabilities \( P(X^i \mid X^{pa(i)}) \) as in the factorised density of a Bayesian network ([Lauritzen, 1996](#)).

### 3.2. Causal validity.

In this section, we formalise the notion of causal validity for graphical local independence models. Similar to most of the causal frameworks for random variables and causal DAGs, our definition reflects that some aspects of the system are considered invariant (or stable, or modular) under certain interventions on other parts of the system ([Dawid and Didelez, 2010](#) [Pearl, 2009](#) [Peters et al., 2016](#) [Spirtes et al., 2000](#)). More specifically, we consider a hypothetical intervention on process \( N^i \) replacing its \( \mathcal{F}^{cl(i)} \)-intensity \( \lambda^i \) by a different
intensity $\tilde{\lambda}^i$ which is typically assumed to be $\mathcal{F}^{V_0}$-predictable, e.g. generated by a subset $V_0$, with the special case where it is predictable just with respect to its own $\mathcal{F}^i$-history. The latter mimics the case of randomisation or exogeneity, while letting the interventional intensity be $\mathcal{F}^{V_0}$-predictable allows for dynamic interventions. An example could be the case where $N^i$ counts the times an individual takes a medication or receives radiotherapy, where a possible intervention could be to increase or decrease the frequency regardless of the individual’s history, or treatment could (dynamically) be intensified after the occurrence of a specific event such as a side-effect. A typical causal question would be to compare two or more such hypothetical interventions, e.g. less frequent and more frequent radiotherapy, regarding their future effects on some other processes, typically a time-to-event outcome such as survival.

While the original model $P$ describes the system’s natural behaviour without intervention, we denote with $\tilde{P}$ the model for the system under such an intervention. The notion of causal validity defined below means that the latter can be obtained from the former by simple substitution of the local characteristic of node $i$ in (3). In a given real-world context this will only be plausible if the system described by its components, the elements of the set $V$, is sufficiently detailed, e.g. in terms of specifying the relevant underlying mechanisms.

**Definition 2.** Let $P(G)$ be a graphical local independence model. The model is called causally valid with respect to an intervention on node $i \in V$ (or on set of nodes $A \subset V$) if the corresponding intervention model $\tilde{P}(G)$ is obtained by replacing (all) $\mu^i$ by $\tilde{\mu}^i$ ($i \in A$) while the local characteristics of the remaining nodes remain the same in $P(G)$ and $\tilde{P}(G)$. Formally, if the joint density of a specific $P \in P(G)$ is given by (3), then the corresponding $\tilde{P}$ is obtained as

$$
\prod_{j \in V \setminus A} Z^j(\mu^j, t) \prod_{i \in A} Z^i(\tilde{\mu}^i, t).
$$

As the above definition of causal validity is based on interventions that replace intensities, it can be regarded as a ‘weak’ notion of causality in contrast to ‘strong’ notions that are based on replacing equations in structural systems, e.g. in causally interpreted stochastic differential equations (Hansen and Søkol, 2014; Mogensen et al., 2018).

A causally valid local independence model without processes, only baseline variables, reduces to a (locally) causal DAG (Pearl, 2009). Further, in the case of variables, we note that different choices for (3) can be probabilistically equivalent but imply different causal relations:
while both $P(X^1, X^2) = P(X^1|X^2)P(X^2)$ and $P(X^1, X^2) = P(X^2|X^1)P(X^1)$, only one of the two (if any) factorisations, corresponding to $X_1 \leftarrow X_2$ or $X_1 \rightarrow X_2$, can be causally valid, i.e. either an intervention on $X^2$ affects $X^1$ or vice versa. For processes, however, the ordering is explicit in ‘time’ so that the main issue is whether the past on the included processes and variables in $\mathcal{V}$ contains sufficient information to warrant causal validity.

### 3.3. Example of how causal validity can fail. Consider an example with two counting processes $N^1$ and $N^2$, where marginally $N^2$ is locally independent of $N^1$ but the true underlying causal structure is such that an intervention on $N^1$ does affect the intensity of $N^2$.

To see this, let $U$ be a binary variable with $P(U = 1)/P(U = 0) = \gamma$. Let the intensities for $N^1$ and $N^2$ w.r.t. $\mathcal{F}_t^{N^1,N^2,U}$ be given by

\[
\lambda^1_t := Y^1_t (U + 1) \\
\lambda^2_t := Y^2_t \left\{ U + g(s, N^1_{s-}) (1 - Y^1_{s-}) + 1 \right\},
\]

where $Y^1_s := I(N^1_{s-} < 1), Y^2_s := I(N^2_{s-} < 1)$ and

\[
g(t, x) := \gamma \left\{ \frac{1 - 2e^{-(x-t)}}{1 + 2\gamma e^{-(x+t)}} \right\}(\gamma + e^{2t}).
\]

Suppose that the model for $(N^1, N^2, U)$ is causally valid under an intervention $\tilde{\lambda}^1$ that prevents $N^1$ from jumping. Hence, the interventional density $\tilde{P}$ satisfies $P(U = i) = \tilde{P}(U = i)$, and $\lambda^2$ remains the intensity for $N^2$ under $\tilde{P}$ (where $g(s, N^1_{s-}) = g(s, 0)$ always). The model is therefore causally valid with respect to the following local independence graph:

\[
\begin{array}{c}
U \\
\downarrow \\
N^1 \\
\downarrow \\
N^2
\end{array}
\]

Under $\tilde{P}$ one can say that the $U \rightarrow N^1$ arrow is deleted.

Assume now that $U$ is ignored, maybe because it is an unknown latent variable. A few computations and the Innovation Theorem yield that (writing $\mathcal{F}^{1,2}$ instead of $\mathcal{F}^{(N^1,N^2)}$)

\[
E_P(\lambda^2_t|\mathcal{F}^{1,2}_{t-}) = Y^2_t \left\{ \frac{2\gamma + e^{2t}}{\gamma + e^{2t}} \right\} + \left\{ \frac{(1 - Y^2_t)\gamma}{(\gamma + e^{2t})(2\gamma e^{-2t} + 1)} \right\}
\]

\[
E_P(\lambda^1_t|\mathcal{F}^{1,2}_{t-}) = Y^1_t \left\{ \frac{2\gamma + e^{2t}}{\gamma + e^{2t}} \right\} + \left\{ \frac{(1 - Y^1_t)\gamma}{(\gamma + e^{2t})(2\gamma e^{-2t} + 1)} \right\}
\]
This implies that marginally over \( U \), \( N^2 \) is locally independent of \( N^1 \), but not vice versa, implying the local independence graph

\[
N^1 \leadsto N^2.
\]

If interpreted causally this suggests that an intervention on \( N^1 \) should not affect \( N^2 \). However, with the true causal structure from above we obtain for an intervention that prevents \( N^1 \) from jumping that

\[
E_P(\lambda_t^2 F_{t-}^{1,2}) = Y_t^2 \frac{2\gamma + e^t}{\gamma + e^t},
\]

showing that the subprocess \((N^1, N^2)\) is not causally valid since \( E_P(\lambda_t^2 F_{t-}^{1,2}) \neq E_{\tilde{P}}(\lambda_t^2 F_{t-}^{1,2}) \).

The example demonstrates that causal validity is typically only plausible when the multivariate system of processes and variables considered contains sufficient information on ‘common causes’ even if they are latent, such as the variable \( U \) above. In the context of causal DAGs, the assumption that there are no omitted variables is known as ‘causal sufficiency’ (Hernán and Robins, 2020; Spirtes et al., 2000). As we will see in Section 4, certain variables or processes can, however, be ignored without destroying causal validity.

The above example is somewhat extreme, as it not only violates causal sufficiency but is also constructed to violate faithfulness (cf. Remark 2): We cannot read off from the true graph on \((N^1, N^2, U)\) that \( N^2 \) is (marginally) locally independent of \( N^1 \). Causal validity would also be violated in any other example where \( E_P(\lambda_t^2 F_{t-}^{1,2}) \neq E_{\tilde{P}}(\lambda_t^2 F_{t-}^{1,2}) \).

3.4. Re-weighting: Likelihood-Ratios and Positivity. The hypothetical regime described by \( \tilde{\mu} \) can in principle be arbitrary and should be chosen to suit the considered, practically relevant, intervention. However, if we want to learn about the hypothetical regime from data obtained under an observational regime, the two cannot be ‘too different’ from each other. To formalise this we demand absolute continuity \( \tilde{P} \ll P \), i.e for every event \( H \in F_T \) with \( P(H) > 0 \) we also have that \( P(H) > 0 \). The following proposition shows that this is closely linked to the existence of a likelihood-ratio process which re-weights the observational distribution \( P \) into the interventional distribution \( \tilde{P} \).

**Proposition 1.** Let \( P(G) \) be a local independence model. Consider a hypothetical intervention on component \( N^* \) with \( F^V \)-intensity \( \lambda^* \), and that this intervention imposes the new intensity
\( \tilde{\lambda}^* := \rho \cdot \lambda^* \) where \( \rho \) is a non-negative and predictable process. Let

\[
W_t := \prod_{s \leq t} \rho^* \exp \left\{ - \int_0^t (\rho_s - 1) \lambda^*_s ds \right\}.
\]

The following statements are equivalent:

1. \( \mathcal{P}(G) \) is causally valid with respect to an intervention on \( N^* \), and for any \( P \in \mathcal{P} \), with corresponding interventional \( \tilde{P} \in \tilde{\mathcal{P}} \), we have \( \tilde{P} \ll P \) on \( \mathcal{F}_T \).
2. We have that

\[
E_{\tilde{P}}(H) = E_P(W_t H)
\]

for every \( \mathcal{F}_t \)-measurable variable \( H \) and \( t \leq T \).

The proof is given in Appendix C. The proposition shows that weighting the events before \( t \) according to \( W_t \) provides the probabilities in the hypothetical situation under the envisaged intervention. The causal validity of the system ensures the simple structure of \( W \) in (7): it only depends on the local characteristic of the intervened node itself.

If causal validity holds, then \( \tilde{P} \ll P \) if and only if the process \( W \) is uniformly integrable on \([0, T]\). There exist several different conditions that imply uniform integrability, see Jacod and Shiryaev (2003, Theorem IV 4.6) and Røyseland (2011) or Kallsen and Shiryaev (2002) for more general results.

The conditions that are most relevant for us, translate into upper boundaries on the predictable processes \( \rho_t = \frac{\lambda^*_t}{\lambda^*_t} \) and \( |\tilde{\lambda}^*_t - \lambda^*_t| \). Such upper boundaries can also be seen as generalisation of the positivity condition that is usually assumed (Hernán and Robins, 2020, 3.3). Moreover, the weights (7) can further be regarded as continuous-time version of the stabilised inverse probability of treatment weights for discrete-time marginal structural models (Hernán et al., 2000; Robins et al., 2000).

As a consequence and as addressed in Section C when \( W \) is known or identified from the observable data, we can carry out statistical analyses of the hypothetical scenario by using weighted averages or weighted regression analyses. It may then be desirable to impose further restrictions on how \( \tilde{\lambda}^* \) and \( \lambda^* \) are allowed to differ so that the weights are well-behaved for stable statistical inference (Røyseland, 2011, 2012).
4. Causal Validity under Marginalisation

Identifiability is at the core of many statistical problems, especially missing data, latent variables and causal inference problems (Manski, 2003; Shpitser and Pearl, 2006). In brief, a parameter $\xi$, being a function of a distribution $P$ in a model $\mathcal{P}$, is said to be identifiable from incomplete information $\mathcal{G}$ if it can uniquely be determined from $P|\mathcal{G}$ for every $P$ in $\mathcal{P}$ (see Appendix B for a more formal treatment of identifiability).

A causal parameter $\xi$ is now a function of the interventional distribution $\tilde{P} \in \tilde{\mathcal{P}}$ resulting from replacing the local characteristics of a given node, as explained above (Definition 2). For example, we may be interested in some aspect of the survival curve under a specific intervention on some treatment process. A causal parameter always induces another parameter $\tilde{\xi}$ in the original model obtained by first mapping $P$ into $\tilde{P}$ using the above likelihood-ratio (7), and then applying $\xi$, i.e. $\tilde{\xi}(P) = \xi(\tilde{P})$. Thus, we say that a causal parameter is identifiable from incomplete information $\mathcal{G}$ if $\tilde{\xi}$ is identifiable from $\mathcal{G}$.

4.1. Eliminability. The following definition of eliminable processes characterises graphically when certain subprocesses (or baseline variables) can safely be ignored without destroying certain aspects of the causal local independence structure. It combines the notions of ‘sequential randomisation’ and ‘sequential irrelevance’ of Dawid and Didelez (2010). Eliminability is then used to establish our key results on identifiability.

We require some notation, first. Here, as before, we are interested in intervening on a process $N^*$ and consider its effect on a set of outcome processes $N_0$, both exclude baseline variables. Moreover, an intervention on $N^*$ does not affect baseline variables as the intervention takes place after baseline. Hence, the marginal distribution on the baseline variables $B$ is the same as the corresponding marginal under an intervention, i.e. $P|_{xB} = \tilde{P}|_{xB}$. However, we allow for baseline variables as well as processes in the set over which we want to marginalise.

Definition 3. Let $G$ be a local independence graph with nodes $\mathcal{V} = \mathcal{V}_0 \cup \mathcal{U}$ for $\mathcal{V}_0 = N_0 \cup B_0$ with $N_0 \subset \mathcal{N}$ and $B_0 \subset B$; let $N^* \in N_0$, and $N_0^{\setminus x} = N_0 \setminus \{N^*\}$. Then we say that, in $G$, the set $\mathcal{U}$ is eliminable with respect to $(N^*, \mathcal{V}_0^{\setminus x})$ if it can be partitioned into a sequence of sets $\mathcal{U}_1, \ldots, \mathcal{U}_K$ such that, for each $k = 1, \ldots, K$, either

$$\mathcal{U}_k \not\rightarrow_G N_0^{\setminus x} | (\mathcal{V}_0, \tilde{\mathcal{U}}^{k+1})$$
or

\[(10) \quad \mathcal{U}_k \rightarrow_G N^* \mid (V_0, \mathcal{U}^{k+1}), \]

holds. Here \(\mathcal{U}^{k+1} = (\mathcal{U}_{k+1}, \ldots, \mathcal{U}_K)\) and \(\mathcal{U}^{K+1} = \emptyset\).

The proposition below shows that causal validity regarding an intervention on \(N^*\) is retained when ignoring (i.e. marginalising over) eliminable sets \(\mathcal{U}\). This is related to and a considerable generalisation of the ‘non-informative treatment assignment’ proposed by [Arjas and Parner (2004)] in the context of marked point processes; the property of eliminability also has some similarity to some principles of the selecting covariates to adjust for confounding in DAGs [VanderWeele and Shpitser, 2011; Witte and Didelez, 2019]. An immediate implication is that in case of eliminability, the likelihood ratio in the subsystem and hence any corresponding causal parameter is identified from \(\mathcal{F}^{V_0}\) (see section 4.2 below). When processes are unobservable it can be helpful to reassure ourselves that they are eliminable to ensure identifiability from observables.

**Proposition 2.** Consider a local independence model \(\mathcal{P}(G)\). Let the nodes be partitioned as in Definition 3. Assume causal validity with respect to an intervention on the process \(N^* \in \mathcal{N}_0\), replacing its \(\mathcal{F}^V\)-intensity \(\lambda^*\) by a \(\mathcal{F}^{V_0}\)-intensity \(\tilde{\lambda}^*\).

If \(\mathcal{U}\) is eliminable with respect to \((N^*, V_0^*)\) in \(G\), then the model restricted to \(\mathcal{F}^{V_0}\) (i.e. marginally over \(\mathcal{U}\)) is also causally valid with respect to the same intervention.

The proof of Proposition 2 is given in Appendix D. The conditions (9) and (10) characterise types of processes that can be ignored without destroying causal validity. Consider for instance the local independence graph

\[U_1 \rightarrow N^* \rightarrow N^y \leftarrow U_2,\]

assuming causal validity with respect to an intervention on \(N^*\). First, by \(\delta\)-separation (9) we see that \(N^y\) is locally independent of \(U_1\) given \((N^*, U_2, N^y)\). Second, with (10), we find that \(N^*\) is locally independent of \(U_2\) given \(N^y, N^*\). Hence, the submodel on \((N^*, N^y)\) is causally valid with respect to an intervention on \(N^*\) as long as this intervention does not depend on \((U_1, U_2)\); the model essentially asserts that there is no confounding of \((N^*, N^y)\) regardless of whether \((U_1, U_2)\) are observed.

Further basic examples where \(U\) can be ignored, are described by the local independence graphs

\[N^* \leftarrow U \leftarrow N^y \quad \quad N^* \rightarrow U \rightarrow N^y.\]
In the first case condition (9) holds, in the second condition (10) of Proposition 2. Here, $U$ could also be a sequence of such processes on directed paths. More examples for local independence models with different structures of eliminable processes can be found in Appendix A.

**Remark 3.** Our result on eliminability is related to the marginalisation considered by Mogensen and Hansen (2020). The authors propose an extended class of local independence graphs, and corresponding $\mu$-separation, which is closed under marginalisation. These more general graphs include bi-directed edges as a possible result of latent processes not shown as nodes in the graph. In our case, if we consider $U$ as latent processes and if they satisfy the conditions of eliminability, then they do not induce any bi-directed edges with endpoints between $N^*$ and $V_0$ in these more general graphs. Moreover, their results can be used to obtain the ‘latent projection’ graph representing the local independence structure after marginalising over $U$ (Mogensen and Hansen, 2020 Definition 2.23 and Theorem 2.24). In the above three examples these would be $N^* \succeq N^y$, $N^* \prec N^y$ and $N^* \rightarrow N^y$, respectively (albeit with bi-directed self loops). However, in general it does not hold that the latent projection over eliminable nodes corresponds to the induced subgraph on the remaining nodes as bi-directed edges could occur between nodes within $N_0$. Latent projections of causal graphs have been used to identify valid adjustment sets (Witte et al., 2020) to which we return in section 6. We briefly comment on the projection graphs for the examples (16,17) in Appendix A.

4.2. **Identifiability and Likelihood Ratio.** The above Proposition 2 immediately implies that together with $\tilde{P} \ll P$ the likelihood ratio

$$\frac{d\tilde{P}|_{\mathcal{F}^{V_0}}}{dP|_{\mathcal{F}^{V_0}},}$$

coincides with the weights of equation (7) with $\lambda^*_t$ being the $\mathcal{F}^{V_0}$-intensity of $N^*$. Hence, as a key implication of Proposition 2 we obtain that any causal parameter $\xi$ that is a function only of $\tilde{P}|_{\mathcal{F}^{V_0}}$ is identified from $\mathcal{F}^{V_0}$ without requiring information on $U$.

Continuing the above example with graph $U_1 \rightarrow N^* \succeq N^y \leftarrow U_2$: Assume $N^*$ is a treatment process indicating start of treatment and $N^y$ a disease process, e.g. indicating a cardiovascular event. Then $U_1$ might be a process that affects the availability of the treatment but nothing else, e.g. indicating a shortage in the pharmacy; $U_2$ might relate to events that affect the disease process but not the availability of, or decision to start, treatment, e.g. a change at the job. If we are interested in the effect of, say, early versus late start of treatment on cardiovascular...
problems, we want to be able to ignore $U_1$ and $U_2$. Then, assuming the local independencies implied by the $\delta$-separations in the graph hold, and that $G$ is causally valid, Proposition 2 tells us that the reduced system $N^* \subseteq N^y$ is also causally valid and the likelihood ratio is identified without information on $(U_1, U_2)$. Hence we can identify the desired causal effect by re-weighting according to (7) using the $F_{N^* \subseteq N^y}$–intensity of $N^*$ ignoring $(U_1, U_2)$.

5. IDENTIFIABILITY UNDER CENSORING

The issue of identifiability under right censoring can be seen from two subtly different angles: The approach via filtrations (Aalen et al., 2008) typically assumes there are processes and baseline variables of interest $V_0$ and a separate censoring process $N^c$, where $F^V_{t \cup N^c}$ is the filtration jointly generated by $V_0 \cup \{N^c\}$, $F^V_t$ is generated by $V_0$ alone, i.e. with no information on being censored, and $F^{V_0 \cup N^c, t \land \Lambda}$ being generated by the observable processes, i.e. with everything that is censored being ‘invisible’. Identification is then about the possibility to use only information in $F^{V_0 \cup N^c, t \land \Lambda}$ to infer quantities such as intensities defined with respect to $F^V_t$. However, this presupposes that it is self-evident what real-life situation $F^V_t$ represents, i.e. how there can be no censoring. If censoring simply occurs due to the end of follow-up, then one can say that $F^V_t$ refers to the patients’ health and lives regardless of whether they are being observed in a study or not, and hence regardless of end of follow-up. This point of view underlies the motivation of the assumption of independent censoring (Andersen, 2005; Andersen et al., 1993).

However, when other types of events, such as ‘death from other causes’, ‘treatment switching’, or even just ‘drop-out’ (often combined with a change in medical care) are considered as censoring events then it becomes less clear to what kind of situation the no-censoring filtration $F^V_t$ refers, let alone whether that filtration represents something practically meaningful. A different angle has therefore sometimes been adopted not only for survival analyses, but also in related problems such as missing data, drop-out or competing events (Farewell et al., 2017; Hernán and Robins, 2020; Young et al., 2020): Assume an overall model $P$ for $V$ including $V_0$ and $\{N^c\}$; this is now modified to $\widetilde{P}$ with $\lambda^c$ replaced by $\tilde{\lambda}^c \equiv 0$ while all other local characteristics remain the same. In other words, we assume that a sufficiently rich system $V$ can be conceived, such that the situation of interest, without censoring, can formally be described by a hypothetical intervention that sets the censoring intensity to zero within a causally valid system (cf. Definition 2). This might imply a much more fundamental change than simply hiding or revealing information. We believe that this approach based on ‘preventing’ censoring
facilitates reasoning about the structural assumptions that allow identifiability of quantities in
the uncensored situation, and would also highlight when censoring by certain types of events
may not be practically meaningful. Even if censoring is simply an inability to observe the sys-
tem but does not in itself affect the system, then violation of independent censoring can occur
because censoring is indirecly informative for some hidden or ignored processes, and this can
also easily be read off from local independence graphs thus alerting us to such a violation.

5.1. Independent Censoring and Causal Validity. In this section we link independent cen-
soring to local independence, so that it can be read off from local independence graphs. Further,
we consider a hypothetical intervention on the system to prevent censoring; hence we give fur-
ther conditions for identifiability invoking causal validity.

Independent censoring is often used informally and sometimes confused with stochastic in-
dependence between processes. Here, following the notion of Andersen (2005), we formulate
it in terms of local independence.

**Definition 4.** Let $\mathcal{P}$ be a local independence model with sets of variables or processes $A \subset N, B \subset \mathcal{V}$, and $N^c$ representing the counting process for censoring events. Then censoring is said to be independent for $A$, given $B$, if $A$ is locally independent of $N^c$ given $A \cup B$. In the special case where $A = N \setminus \{N^c\}$ and $B = B$, then we say that the whole model satisfies independent censoring.

**Remark 4.** As local independence can be read off from a local independence graph via $\delta$-
separation, the above can be checked graphically. Let $\mathcal{P}(G)$ be a local independence model
on a graph $G$ with sets of nodes $A \cup B \cup N^c \subset \mathcal{V}$. Censoring is independent for $A$, given
$A \cup B$, if $N^c$ is $\delta$-separated from $A$ by $A \cup B$ in $G$. The whole model on $\mathcal{V}$ satisfies independent
censoring if the node $N^c$ has no children in $G$. Moreover, the submodel induced by $A \cup B \cup \{N^c\}$
is subject to independent censoring if $N^c$ is $\delta$-separated from $A \cup B$ by $A \cup B$ alone in $G$ (or,
more explicitly, if $N^c \not\rightarrow G N \cap (A \cup B) | A \cup B$).

In Appendix E (Lemma 3) we prove that independent censoring ensures that the intensities
with respect to the uncensored filtration are identifiable. We further argue that as long as there
is a non-zero probability to observe the event before censoring (e.g. by the end of follow-up)
there exists de-censoring maps $\zeta$ to obtain $P$ on $\mathcal{F}_t^V$ from information restricted to $\mathcal{F}_t^{V \cup N^c}$
GRAPHICAL CRITERIA FOR THE IDENTIFICATION OF MARGINAL CAUSAL EFFECTS IN CONTINUOUS-TIME SURVIVAL AND EVENT-HISTORY ANALYSES

(see Remark 6 in Appendix E), i.e.

$$\zeta \left( P \big| \mathcal{F}_{T \cup N^c} \right) = P \big| \mathcal{F}_{T}.$$  \hspace{1cm} (11)

The above formulation via the de-censoring map is very general; in practice it is typical to show that a particular method of estimation is consistent for the desired parameter under independent censoring within a (semi-)parametric model. For our purposes, we choose to stay with the more general framework of identification just assuming the existence of intensities.

However, as can be seen from Example 3.3 (e.g. if $N^1$ were a censoring process) independent censoring is not sufficient to also ensure identifiability of a system in which censoring is prevented as it would yield the wrong intensity (6). Additionally, we need causal validity with regard to an intervention on censoring, as formalised next.

**Proposition 3.** Let $\mathcal{P}(G)$ be a local independence model on $\mathcal{V}$ subject to independent censoring with bounded intensity for censoring; additionally assume it is causally valid with respect to an intervention that prevents censoring. If $N^c$ is $\delta$-separated from $N_0$ given $V_0$ in $G$, then the marginal model on $V_0 \cup \{N^c\}$ satisfies independent censoring and retains causal validity with respect to the same intervention on $N^c$.

The proof is given in Appendix F. Put together, the above results mean that when we have independent censoring we can recover the uncensored $\mathcal{F}_{V_0 \cup N^c}$-intensities from censored data, and if additionally we have causal validity with regard to an intervention that prevents censoring then these are also the intensities under the interventional distribution $\tilde{P}$ where censoring is prevented. Note that the results are general in that they do not rely on any particular structure for the intensities other than that they exist.

5.2. ‘Randomising’ Censoring. As can be seen from its proof, Proposition 3 remains true for an intervention on $N^c$ that imposes a different $\mathcal{F}_{V_0 \cup N^c}$-intensity for censoring; ‘preventing’ censoring is just a special case. We will loosely refer to censoring interventions that impose an $\mathcal{F}_{V_0 \cup N^c}$-intensity as ‘randomising’ censoring. This may not be an intervention that is in itself of practical relevance, but, as mentioned in section 3.4, leads to more stable weights such as (12) in the following section. In other words, for re-weighting we want to consider intervention intensities that are ‘not too different’ from the observational censoring intensity. The intervention that prevents censoring, corresponding to setting the censoring intensity to zero, may not yield efficient estimation. Formally, we posit the following.

---

20
Remark 5. We assume that if a model is causally valid with respect to an intervention that prevents censoring, then it is also causally valid with respect to an intervention that randomises censoring.

The following corollary justifies that we can essentially equate the two types of interventions on censoring, as an intervention that randomises censoring yields the same hypothetical distribution as one that prevents censoring when restricted to $\mathcal{F}^{V_0}$.

**Corollary 1.** Let $\mathcal{P}(G)$ be as in Proposition 3 and assume that the model is causally valid with respect to prevention of censoring, with $P^p$ being the model in which censoring is prevented. Let $P^r$ be a model where we have imposed an $\mathcal{F}^{V_0 \cup N^c}$-intensity for censoring. Then, we have that

$$P^p|_{\mathcal{F}^{V_0}} = P^r|_{\mathcal{F}^{V_0}} = P|_{\mathcal{F}^{V_0}}.$$

In particular, every parameter on such hypothetical measures restricted to $\mathcal{F}^{V_0}$ is invariant with respect to the choice of censoring intervention.

Together with Lemma 3 (Appendix E) we have that the $\mathcal{F}^{V_0}$-intensity of every $N \in V_0$ is identifiable by the observable censored information and retains its interpretation under a hypothetical scenario where censoring can be prevented. In this case, we do not need to use re-weighting to identify parameters under prevention of censoring. However, in the following Section 6 we consider the case where independent censoring does not necessarily hold with respect to $V_0$ but may require further information, which can only be marginalised out after re-weighting.

6. **Marginal Structural Models and Censoring**

In this section we show how the previous results can all be combined to deal with the case where we aim at estimating the effect of a hypothetical intervention on a treatment or exposure process $N^x$ on one or more outcome processes $N^0_0$ under a further intervention that prevents censoring. Typically, the set $N_0$ would include a survival-type outcome, but can be much more general event-histories such as recurrent events and multi-state processes. Moreover, we now allow the case that additional covariates, baseline or processes, $L$ are observable but are not of interest in the sense that we would like the effect of the treatment intervention on $N_0$ marginally over $L$. This can be regarded as a continuous-time event history analogue to the causal parameter of marginal structural models (Hernán et al., 2000; Robins et al., 2000; Røysland, 2011).
The set $\mathcal{L}$ is typically needed for adjustment if it contains processes that are not eliminable, e.g. time-dependent confounding, such that the local independencies of Propositions 2 and 3 may not hold for $\mathcal{V}_0$ alone. As in discrete time, a continuous-time MSM can be fitted using suitable re-weighting. However, the re-weighting has two aspects: mimicking an intervention that prevents (or randomises) censoring (cf. Remark 5), and an intervention on the treatment process.

Let the stochastic system be described by the following sets of variables and processes

$$\mathcal{V} = \mathcal{V}_0 \cup \mathcal{L} \cup \mathcal{U} \cup \{N^c\}$$

where $\mathcal{V}_0 = \mathcal{B}_0 \cup \mathcal{N}_0$, $N^x \in \mathcal{N}_0$ is a treatment process, $N^c$ the censoring process, $\mathcal{N}_0 \setminus \{N^x\}$ the outcome processes of interest, $\mathcal{L} = \mathcal{B}_\mathcal{L} \cup \mathcal{N}_\mathcal{L}$ are the baseline variables $\mathcal{B}_\mathcal{L}$ and counting processes $\mathcal{N}_\mathcal{L}$ we wish to marginalise out, and $\mathcal{U}$ unobserved variables or processes.

The interventions replace the $\mathcal{F}_{\mathcal{V}}$ intensities of this system by new intensities for $N^c$ and $N^x$. As we cannot observe $\mathcal{U}$ we now give conditions such that we can instead work with the observable intensities, where $\lambda^c$ is the $\mathcal{F}_{\mathcal{V}_0 \cup \mathcal{L} \cup \{N^c\}}$-intensity of $N^c$ with respect to $P$, while $\lambda^x$ denotes the $\mathcal{F}_{\mathcal{V}_0 \cup \mathcal{L} \cup \{N^x\}}$-intensity of $N^x$ with respect to $P$. In contrast, the interventions enforce an $\mathcal{F}_{\mathcal{V}_0 \cup \{N^c\}}$-predictable $\hat{\lambda}^c := \rho^c \cdot \lambda^c$, and an $\mathcal{F}_{\mathcal{V}_0}$-predictable $\hat{\lambda}^x := \rho^x \cdot \lambda^x$ as in Proposition 1. As the following Theorem 1 shows, we can obtain the hypothetical scenario from the observable data under key structural assumptions using the following combined weights

$$W_t = \prod_{s \leq t} (\rho^c_s)^{\Delta N^c_s} \exp \left( - \int_0^t (\rho^c_s - 1) \lambda^c_s ds \right) \prod_{s \leq t} (\rho^x_s)^{\Delta N^x_s} \exp \left( - \int_0^t (\rho^x_s - 1) \lambda^x_s ds \right).$$

The first part of the weight refers to the censoring re-weighting, and is given by $\exp \{- \int_0^t (\rho^c_s - 1) \lambda^c_s ds\}$ before censoring.

**Theorem 1.** With the above notation and set-up, consider a local independence model $\mathcal{P}(G)$. We assume that censoring is independent with respect to $\mathcal{V}$, i.e. $ch(N^c) = \emptyset$ in $G$. We assume causal validity with respect to an intervention that prevents censoring and the additional intervention on the treatment process. Let $\tilde{\mathcal{P}}$ denote the resulting interventional model.

Further, assume

(i) $N^c \rightarrow_G (\mathcal{N}_0, \mathcal{N}_\mathcal{L})|(\mathcal{V}_0, \mathcal{L})$, and
(ii) $\mathcal{U}$ is eliminable with respect to $(N^x, \mathcal{L} \cup \mathcal{V}_0 \setminus \{N^x\})$;

finally, assume the technical conditions that $\rho^c$ and $\rho^x$ are bounded. Then we have:

The interventional distribution $\tilde{\mathcal{P}}$ under both hypothetical interventions (preventing censoring
and intervening on treatment) restricted to the subset $\mathcal{V}_0$ is identified from the observable information $\mathcal{F}_{T \cap C}^{\mathcal{V}_0 \cup L \cup N^c}$ by

$$\tilde{P}|_{\mathcal{F}_{\mathcal{V}_0}^T} = \zeta \left( \left( W_{T \cap C} \cdot P|_{\mathcal{F}_{T \cap C}^{\mathcal{V}_0 \cup L \cup N^c}} \right)|_{\mathcal{F}_{T \cap C}^{\mathcal{V}_0 \cup L \cup N^c}} \right).$$

Thus, the marginal density $\tilde{P}|_{\mathcal{F}_{\mathcal{V}_0}^T}$ is given by re-weighting, marginalising over $L$ and applying a de-censoring map as in (11) (see Remark 6 in Appendix E).

The proof is given in Appendix G. In words, the above theorem states conditions such that any marginal (over $L$) causal parameters are identified from the censored data ignoring $U$, where these causal parameters quantify the effect on $N_0$ of an intervention on $N^x$ while preventing censoring. In particular, with Theorem 1(i), we have independent censoring for $\tilde{P}$ restricted to $\mathcal{V}_0 \cup \{N^c\}$. We can thus use the above re-weighting strategy in standard survival analysis methods to estimate parameters under $\tilde{P}|_{\mathcal{F}_{\mathcal{V}_0}^T}$ (see also Ryalen et al. (2019)).

Below, in Figure 1, we give a graphical example to illustrate Theorem 1. Here, all nodes are processes and $\mathcal{V}_0 = \{N^y, N^x\}$, $L = \{L\}$, $U = \{U^1, U^2, U^3\}$. The example represents a situation of time-dependent confounding by the process $L$: it is affected by, and affects itself the treatment process $N^x$ while also affecting the outcome process $N^y$. We see that censoring is independent in $\mathcal{V}$ as the node $N^c$ is childless. Property (i) can easily be seen via $\delta$-separation; note that while $N^c$ is locally dependent on $U^3$, the latter does not affect the remaining nodes, so that marginally over $U^3$ independent censoring is retained. Property (ii) would also be invalid if $U^1$ or $U^2$ had directed edges pointing at $N^c$. In $G$, the unobservable processes $(U^1, U^2, U^3)$ are eliminable in any sequence. We can verify that $(L, N^y)$ are locally independent of $U^2$ given $(L, N^y, N^x, U^1, U^3)$, and $N^x$ is locally independent of $U^1$ given $(N^x, L, N^y, U^3)$; and further $(L, N^y, N^x)$ are locally independent of $U^3$, so that property (ii) holds. Note that if we modified the example to $L$ being unobservable so that $L = \emptyset$, $U = \{L, U^1, U^2, U^3\}$ then neither (i) nor (ii) of Theorem 1 would hold.

Theorem 1 can also be used in the following way: Let us partition the nodes into

$$\mathcal{V} = \mathcal{V}_0 \cup Z \cup \{N^c\},$$

where $Z$ is any set of baseline variables or additional processes deemed relevant for causal validity. Then, if a subset $L \subset Z$ exists such that Theorem 1 holds with $U = Z \setminus L$, then the
interventional distribution \( \hat{P} \) is identified if \( \mathcal{L} \) can be measured. We leave the development of algorithms that find such \( \mathcal{L} \) for future work.

A slight generalisation of Theorem 1 can be obtained: We considered the intensities \( \lambda^c \) and \( \lambda^x \) of \( N^c \) and \( N^x \) that were measurable with respect to the observed information \( \mathcal{F}^{V_0 \cup \mathcal{L} \cup N^c} \) and \( P \). We could instead accommodate different adjustment sets in the sense of allowing \( \lambda^c \) and \( \lambda^x \) to be intensities with respect to smaller filtrations, say, \( \mathcal{F}^{V_0^c \cup \mathcal{L}^c \cup N^c} \) and \( \mathcal{F}^{V_0^x \cup \mathcal{L}^x \cup N^x} \), respectively, with \( V_0^c, V_0^x \subset V_0 \) and \( \mathcal{L}^c, \mathcal{L}^x \subset \mathcal{L} \): conditions (i) and (ii) still ensure the result. In particular, the likelihood ratio then still coincides with (12).

7. Application: Introducing HPV-Testing to Follow-up Low-Grade Cytology Exams in Cervical Cancer Screening Program in Norway

Cervical cancer is an infrequent end-stage of common cellular changes, starting with minor abnormalities and ranging through more definitely premalignant change to localised invasive and disseminated disease to death. This is an extremely complex process, but being able to detect cancer in its early stages or as precancers, accompanied by prompt appropriate treatment, are key elements of successful cancer screening programs.

Since 1995, Norwegian women 25 to 69 years of age are advised to attend cervical cancer screening every three years for cytology exam, with the objective to identify and treat those with cervical intraepithelial lesion grade 2 or 3 (CIN2+). Some of the cytology exams yield inconclusive results, and since 2005 HPV testing has been used to guide future treatment strategies.

7.1. Which HPV-tests are suitable for secondary screening? The three most common HPV tests in Norway from 2005 to 2010 were AMPLICOR HPV Test, Hybrid Capture2 High-Risk
Figure 2. Local independence graph showing the assumed structure of the HPV-testing scenario.

HPV DNA Test or PreTectTM HPV-Proofer referred to as Amplicor, HC2, and PreTectProofer (Nygård et al., 2014). When used after an inconclusive finding, PreTectProofer negative HPV-tests were more often followed later by a detection of CIN2+ than its competitors suggesting more false-negative tests for PreTectProofer (Haldorsen et al., 2011; Nygård et al., 2014). However, PreTectProofer patients were also subject to more subsequent testing (Nygård et al., 2014), presumably due to the manufacturer’s recommendations. Thus, the apparent false-negative PreTectProofer results might have been due to the higher rate of subsequent testing.

The objective of our analysis is to compare the cumulative incidences of CIN2+ detection in the PreTectProofer group with the other two groups under a hypothetical scenario where an intervention ensures that the PreTectProofer patients are subject to the same rate of subsequent testing as under the other test-types. More formally, let \( \tilde{P} \) denote the distribution under the modified “subsequent testing” intensity and prevention of censoring. The contrast of interest is then given as the difference in cumulative incidence functions over time \( t \),

\[
\tilde{P}(N^y_t = 1 \mid \text{PTP, neg.HPV, inconcl.Cyt}) - \tilde{P}(N^y_t = 1 \mid \text{A/HC, neg.HPV, inconcl.Cyt}).
\]

Under the assumed causal structure described next, this is only not zero if the different HPV-test types have different false-negative rates.

7.2. **Local independences and causal validity.** Figure 2 contains a local independence model for the assumed HPV-testing scenario. Here we have that “latent disease” represents a baseline
variable describing the disease at the time of the HPV-test and cytology. “HPV-test type” is the
HPV-test that accompanies the cytology (binary: PreTectProofer, yes or no). The node “latent
progression” represents a set of counting processes describing the disease’s progression from
the time of the cytology over time. “Subsequent test” is a counting process that ‘counts’ the
first subsequent cytology or HPV-test. The node “CIN2+ histology” represents the counting
process that jumps when CIN2+ is detected. The analysis is restricted to subjects who had an
inconclusive (i.e. ASCUS/LSIL/unsatisfactory) secondary cytology screening and who initially
had a negative HPV-test result, as indicated by the boxed nodes in Figure 2. Individuals are
censored at the end of the follow-up period if there was no occurrence of CIN2+ detection. The
number of deaths was negligible, and is ignored.

Key assumptions are that any testing in itself does not affect the disease progression, but also
vice versa, disease progression does not affect the testing regime. This could be violated if cer-
tain (undocumented) symptoms lead to the initiation of an HPV-test, but this is unlikely in the
present case. The edge “HPV-test type” → “Subsequent test” is due to the observationally dif-
fering subsequent testing rates. In this analysis, we mimic an intervention imposing the same
subsequent testing regime for all the HPV tests, in effect making ”Subsequent test” locally
independent of ”HPV-test type” in the hypothetical scenario. Under \( \tilde{P} \), any association be-
tween type of HPV-test and CIN2+ histology when conditioning on \{“HPV-result”=negative,
“Cytology”=inconclusive\} is then due to unblocked paths "HPV-test type” → “HPV-result”
←“Latent disease” → · · · “CIN2+ histology” which would indicate a tendency to false-negative
results due to the edge “HPV-test type” → “HPV-result”.

We will appeal to Theorem 1. For this we define the sets of nodes

\[ B_0 = \{ \text{Cytology, HPV-test type, HPV result} \} \]

\[ U = \{ \text{Latent disease, Latent progression} \}. \]

Let \( N^x, N^y, N^c \) be counting processes where \( N^x \) counts initiation of “Subsequent test”, \( N^y \)
counts histology finding CIN2+, and \( N^c \) counts censoring events. Thus, \( N_0 = \{ N^x, N^y \} \), and
\( N^c = N^y \) and \( V_0 = B_0 \cup N_0 \). We make the following observations:

- \( N^c \) has no descendants, i.e. censoring is independent with respect to \( V \).
- There are no allowed trails from \( N^c \) to \( V_0 \), so \( N^c \not\rightarrow_G N_0 \mid V_0 \), and condition (ii) from
  Theorem 1 holds.
• Every allowed trail from $\mathcal{U}$ to $N^x$ is blocked by either “Cytology” or “HPV-test type”, both of which are in $B_0$. Hence, $\mathcal{U}$ is eliminable with respect to $(N^x, \mathcal{V}_0 \setminus \{N^x\})$ in $G$, and condition (ii) of Theorem 1 holds.

These points justify the use of Theorem 1, and the $F_{V^0}$-intensity of $N^y$ under $\tilde{P}$ is identified. As $\mathcal{L} = \emptyset$, we have from Proposition 3 that the model restricted to $F_{V^0} \cup N^c$ is causally valid with respect to prevention of censoring and subject to independent censoring. The censoring weights thus equal one, and (12) reduces to

$$W_t = \prod_{s \leq t} (\rho_s^x)^{\Delta N^x_s} \exp \left( - \int_0^t (\rho_s^x - 1) \lambda_s^x \, ds \right)$$

in this example.

7.3. Analysis. We consider data from the Cancer Registry of Norway containing 1736 subjects (878 in the PreTectProofer group and 858 in the Amplicor/HC2 group) with inconclusive cytology and negative initial HPV test recorded in 2005-2010 until CIN2+ or end of 2010. We calculate the probability of having CIN2+ detected by time $t$ in a situation where individuals receive “subsequent test” with intensity $\tilde{\lambda}^x$ equal to the intensity in the (pooled) Amplicor/HC2 group. The probability of interest is calculated by one minus the weighted Kaplan-Meier estimator $\hat{S}^w$, given by

$$\hat{S}^w_t = \prod_{T_i \leq t} \left( 1 - \frac{\tilde{W}^i_{T_i} Y^i_{T_i}}{\sum_j \tilde{W}^j_{T_i} Y^j_{T_i}} \right),$$

where $\tilde{W}^i$ are estimates of (12), the $T_i$’s the observed detection times of CIN2+, and the $Y^i_{T_i}$’s are at-risk indicators (not censored) at time $t$ in a given group.

For the Amplicor/HC2 group, the “subsequent test” intensity is equal to the observational intensity, and each $W^i$ is equal to one. Thus, (14) reduces to the standard Kaplan-Meier estimator with CIN2+ occurrence as the endpoint.

To estimate this probability in the PreTectProofer-group, we first need estimates $\tilde{W}^i$. The $F_{V^0}$-intensity of $N^x$ is only a function of “HPV-test type” (due to local independences implied by the graph). We thus obtain the estimator

$$\tilde{W}^i_t = 1 + \int_0^t \tilde{W}^i_{s^-} (\theta_s - 1) dN^x_s - \int_0^t \tilde{W}^i_{s^-} I(N^x_s = 0) d(\hat{A}^x_s - \hat{A}^x_{s^-}),$$

where $\theta_s = \frac{\hat{A}_s^x - \hat{A}_{s^-}^x}{\hat{A}_s^x - \hat{A}_{s^-}^x}$ for a smoothing parameter $b$, and $\hat{A}^x_s$ and $\hat{A}^x_{s^-}$ are the Nelson-Aalen estimators for subsequent test initiation applied to the Amplicor/HC2 group and the PreTectProofer group, respectively. We calculate these weights using the R package ahw. The weighted Kaplan-Meier estimator (14) is consistent for a bandwidth parameter $b = b(n)$ depending on
FIGURE 3. Upper: Proportion CIN2+ detected after the secondary screening with ASCUS/LSIL/unsatisfactory cytology and negative HPV-test. Lower: Difference between the proportions of detected CIN2+ in the PreTectProofer-group and Amplicor/HC2-group when imposing the Amplicor/HC2 group’s subsequent testing regime on both groups. We obtained 95% pointwise confidence intervals using a bootstrap sample of 400.
the sample size $n$ with $b(n) \xrightarrow{n \to \infty} 0$ and $\sup_{s \leq T} \frac{\alpha^2}{\sigma^2} < \infty$; see Ryalen et al., 2018b, 2019, respectively Theorems 1 & 2, and Theorem 1).

The R implementation of the above, applied to a simulated data set with similar features, is available on the GitHub repository github.com/palryalen/paper-code.

7.4. Results. The cumulative incidences of CIN2+ detection are shown in Figure 3. In the upper panel, we see three curves: for PreTectProofer without and with re-weighting, and the non-PreTectProofer group without weighting. Thus, the proportion of CIN2+ detected in the PreTectProofer group is somewhat lower under the hypothetical subsequent-testing regime than observationally, i.e. without an intervention. However, the estimated contrast (13), shown in the lower panel, is still significant. Under the structural assumptions we made, this gives support to the interpretation that there are genuinely more false-negative HPV-test results in the PreTectProofer group than with the other test types, and that the greater CIN2+ numbers are not only a consequence of more frequent subsequent testing.

8. Conclusions and Discussion

We have proposed a formal graphical approach to causal reasoning in survival and more general event-history settings in continuous time. As we have seen, this requires a dynamic notion of independence, i.e. local independence, corresponding generalised graphs and $\delta$-separation. The key principle of causal diagrams, i.e. invariance (or stability or modularity (Dawid and Didelez, 2010; Pearl, 2009; Peters et al., 2016)) with respect to a hypothetical intervention, can then be extended to these local independence graphs, a property which we termed causal validity. In contrast to the common approach in causal inference, where interventions fix a variable at a single value, this is less plausible in continuous time and we consider instead interventions that modify the intensity of a treatment process thus ensuring well-behaved weights according to Proposition 1. This notion is similar to that of ‘randomised plans’ (Gill and Robins, 2001) or stochastic interventions (Dawid and Didelez, 2010; Diaz and van der Laan, 2018); and it is more explicit than that of ‘causal influence’ (Commenges and Gégout-Petit, 2009). Further, our change of treatment intensity could be thought of as a stochastic change of time: one can construct a stochastic time-change $\varrho$ such that the $P$-intensity of $N^x_\varrho$ coincides with the $\tilde{P}$-intensity of $N^x$ (Andersen et al., 1993, II 5.2.2). While the predominant way of formalising the effect of an intervention is based on potential outcomes, we have chosen to simply compare the observational and the interventional distributions, $P$ and $\tilde{P}$; this is similar in spirit to other
causal frameworks, for instance by Dawid and Didelez (2010); Peters et al. (2016); Spirtes et al. (2000).

We derived graphical criteria to characterise which types of processes are eliminable while retaining identifiability of certain causal relations. Vice versa, this means that causal effects of the treatment process on the outcome processes are identified as long as the non-eliminable processes are observable. The criterion is thus sufficient for identifiability, and we conjecture that necessary conditions analogous to Shpitser and Pearl (2008) will be difficult to derive for the general continuous-time case. In future work it will be interesting to generalise our results to the extended local independence graphs of Mogensen and Hansen (2020) which are closed under marginalisation and which can be obtained by projecting over unobservable processes.

We have further formalised, and characterised graphically, the notion of independent censoring, where we argued that inference for the uncensored case additionally requires causal validity with regard to an intervention that prevents censoring. While this has been well-recognised in the causal inference literature for longitudinal settings with drop-out (Hernán and Robins, 2020), it seems less appreciated in more traditional approaches to survival analysis; an exception is recent work by Rytgaard et al. (2021) on continuous time-settings making explicit that the target estimand involves an intervention to prevent censoring. Finally we derived Theorem 1 which enables identification of causal parameters via re-weighting to account for time-dependent confounding as well as for dependent censoring in continuous-time settings, thus generalising results well-known from discrete-time marginal structural models (Hernán et al., 2000; Robins et al., 2000). Marginal structural models are often associated with the problem of time-dependent confounding but can also be used in other scenarios (Joffe et al., 2004). In the application in Section 7, Theorem 1 was used to establish that time-dependent confounding was not an issue (as \( \mathcal{L} \) was the empty set) and that a fairly simple weighting process sufficed. Similarly, Ryalen et al. (2018a) used a continuous-time MSM to compare the treatment regimens radiotherapy and radical prostatectomy.

Our results concern general graph-based causal identifiability in the class of multivariate counting processes, including e.g. multi-state processes, and do not rely on any particular (semi)-parametric class of models. While in many practical situations concrete estimation and inference will rely on additional modelling assumptions, the data example of section 7 allowed for non-parametric estimation. In addressing identifiability, we have chosen the re-weighting route which appears natural in view of the simplicity of Proposition 1 and corresponds to a change of measure technique. In longitudinal causal inference settings, the g-computation
formula is the predominant identifying functional. However, g-computation appears hard in entirely general continuous time settings, as discussed by [Gill (2001)](#), but has been applied within fully parametric approaches [Gran et al., 2015](#). We believe that our graphical causal reasoning can alternatively be combined with g-estimation which has been considered in continuous-time settings [Lok et al., 2004](#), [Lok, 2008](#), or targeted minimum-loss estimation [Rytgaard et al., 2021](#). We argue that our approach complements these methods because the graphical representation and explicit discussion of eliminability strengthens the plausibility of the required structural assumptions about the continuous-time processes.

**Appendix A. Examples: Local Independence Graphs**

In the graph (15), below, we consider two baseline variables $X, Z$ and two counting processes $N^a, N^b$. Due to the edge $X \rightarrow Z$ there is no independence between the baseline variables. Both variables are locally independent of $N^a$ and $N^b$ jointly or individually by definition. The absence of an edge from $N^a$ to $N^b$ implies the local independence $N^a \not\rightarrow N^b | (X, Z, N^b)$. However, as can be read of with $\delta$-separation, it does not generally hold in this local independence model that $N^a \not\rightarrow N^b | N^b$ nor that $N^a \not\rightarrow N^b | (N^b, Z)$ but it does hold that $Z$ can be ignored to obtain $N^a \not\rightarrow N^b | (X, N^b)$. Thus if $N^a$ were a censoring process, then the model as a whole and the submodel $(N^a, N^b, X)$ would satisfy independent censoring, but ignoring $X$ would violate independent censoring, cf. Definition 4.

![Graph](15)

The following are examples of local independence graphs where the processes in $\mathcal{U}$ are eliminable. In (16) we see that the ordering $U_{1,2}, U_3$ satisfies Definition 3 first property (9) and then property (10); by symmetry $U_{1,3}, U_2$ also works (but $U_2, U_3, U_1$, for instance, would not be a suitable ordering). The projection graph (see Remark 3) would just consist of $N^x$ and $N^y$ with two edges linking them.
The graph in (17) is an example with a bivariate outcome process $N^y = (N^1, N^2)$; here the unobserved process is eliminable as (10) applies. The projection graph would contain a bidirected edge between $N^1$ and $N^2$ but this is not relevant for our purposes, here.

APPENDIX B. IDENTIFIABILITY

We need to formalise what we mean by identifiability in our context before we present the proof of Theorem 1. Our definition of identifiability given below is in the spirit of previous definitions (Manski (2003); Shpitser and Pearl (2006)), but we re-state it within our context and notation as it is central to our results. We start by clarifying the very general notion of ‘parameter’ that we employ.

Consider a collection of probability measures $\mathcal{P}$ on a $\sigma$-algebra $\mathcal{F}$. We will consider computable quantities that can be represented by maps

$$\xi : \mathcal{P} \to \Xi.$$  

(18)

Even if this model is not parameterised, since we do not rely on maps $\Theta : \mathbb{R}^n \to \mathcal{P}$, we will somewhat ambiguously refer to maps like (18) as parameters. Note that we also consider parameters that are random. For instance, likelihood-ratios and predictable intensity processes can thus be seen as parameters.

Suppose we are not able to acquire all the potential information $\mathcal{F}$ about the whole stochastic system, but only some abbreviated adaptation $\mathcal{G}$ represented by a sub $\sigma$-algebra. We would now like to know if it is possible to learn the value of the parameter $\xi$, based only on the incomplete information $\mathcal{G}$. 

32
The probability distributions for the observable information, according to the model $\mathcal{P}$, is given by restricting every $P \in \mathcal{P}$ to $\mathcal{G}$. Whenever $P$ is a distribution in $\mathcal{P}$, let $P|_{\mathcal{G}}$ denote its restriction to $\mathcal{G}$ and let $\mathcal{P}|_{\mathcal{G}}$ denote the set of all such restrictions. The usual notion of identifiability now translates into the following.

**Definition 5.** A parameter $\xi : \mathcal{P} \rightarrow \Xi$ is identifiable with respect to the incomplete information $\mathcal{G}$ if $\xi(P)$ can be uniquely determined from $P|_{\mathcal{G}}$, i.e. there exists another map $\eta : \mathcal{P}|_{\mathcal{G}} \rightarrow \Xi$ such that

$$\xi(P) = \eta(P|_{\mathcal{G}}),$$

for every $P$ in $\mathcal{P}$.

With regard to a causal parameter, we think of the intervention changing the local characteristics as a transformation $P \mapsto \tilde{P}$, and $\tilde{\mathcal{P}} := \{\tilde{P} | P \in \mathcal{P}\}$ defines a non-parametrised model for the hypothetically intervened scenario. Recall also that we consider transformations where $\tilde{P}$ can be achieved through re-weighting $P$, i.e. $\tilde{P} = \frac{d\tilde{P}}{dP} \cdot P$. If the underlying model is causal, then we will refer to any parameter $\tilde{\xi} : \tilde{\mathcal{P}} \rightarrow \Xi$ as a causal parameter. Such a parameter always induces another parameter of the original model, namely $\tilde{\xi} : \mathcal{P} \rightarrow \Xi$, where $\tilde{\xi}(P) = \xi(\tilde{P})$. The induced parameter $\tilde{\xi}$ is obtained by first performing the transformation $P \mapsto \tilde{P}$ and then applying $\xi$ to the transformed distribution $\tilde{P}$. Pearl’s notion of identifiability (Pearl, 2009, Definition 3.2.4) now translates into the following:

**Definition 6.** A causal parameter $\xi : \tilde{\mathcal{P}} \rightarrow \Xi$ is identifiable with respect to the incomplete information $\mathcal{G}$ if the induced parameter $\tilde{\xi} : \mathcal{P} \rightarrow \Xi$ is identifiable with respect to $\mathcal{G}$ in the sense of Definition 5.

**APPENDIX C. PROOF OF PROPOSITION 1**

**Proof.** To see that (1) $\implies$ (2), we note that the local characteristics for the baseline variables under $P$ coincide with the respective local characteristics under $\tilde{P}$. This means that $\tilde{P}|_{\mathcal{F}^0} = P|_{\mathcal{F}^0}$. Moreover, note that the causal validity means that $M_i^t := N_i^t - \int_0^t \lambda_i^s ds$ is a local $\mathcal{F}$-martingale with respect to $\tilde{P}$ for every $i \neq *$. On the other hand, we have already assumed that $\tilde{M}_i^t := N_i^t - \int_0^t \rho_i^s \lambda_i^s ds$ is a local $\mathcal{F}$-martingale with respect to $\tilde{P}$. Since we assume that $\tilde{P} \ll P$, (Jacod and Shiryaev, 2003, Theorem III.5.43) tells us that the likelihood-ratio process coincides with $W_t$. This means that (2) also holds.
Conversely, assume that (2) holds. Note that this immediately implies \( \bar{P} \ll P \) on \( \mathcal{F}_T \). Moreover, let \( K^*_t := \int_0^t (\rho_s - 1) dM^*_s \). We know (Protter, 2005, Theorem II.37) that \( W \) is the (unique) solution of the integral equation \( W_t = 1 + \int_0^t W_s \, dK^*_t \). Now, whenever \( h \) is a bounded and \( \mathcal{F} \)-predictable process, we let \( H = \int_0^T h_s \, dM^*_s \), and note that (2) implies that
\[
\begin{align*}
E_{\bar{P}} \left( \int_0^T h_s \, dM^*_s \right) &= E_P \left( W_T \int_0^T h_s \, dM^*_s \right) \\
&= E_P \left( \int_0^T h_s W_s \, dM^*_s + \int_0^t \int_{s^-}^s h_r \, dM^*_r W_s \, dK^*_s + \int_0^T h_s W_s \, d[K^*, M^*]_s \right) \\
&= 0,
\end{align*}
\]

since \( M^i \) and \( M^* \) (and hence \( K^* \)) are local martingales with respect to \( P \), and \( K^* \) and \( M^i \) are orthogonal.

On the other hand, we have that
\[
\begin{align*}
E_{\bar{P}} \left( \int_0^T h_s \, d\tilde{M}^*_s \right) &= E_P \left( W_T \int_0^T h_s \, d\tilde{M}^*_s \right) \\
&= E_P \left( \int_0^T h_s W_s \, d\tilde{M}^*_s + \int_0^t \int_{s^-}^s h_r \, d\tilde{M}^*_r W_s \, dK^*_s + \int_0^T h_s W_s \, d[K^*, \tilde{M}^*]_s \right) \\
&= E_P \left( \int_0^T h_s W_s \, d\tilde{M}^*_s + \int_0^T h_s W_s (\rho_s - 1) N^*_s \right) \\
&= E_P \left( \int_0^T h_s W_s \, d\tilde{M}^*_s \right) = 0,
\end{align*}
\]

since \( \tilde{M}^* \) is a local martingale with respect to \( P \). This means that \( \tilde{M}^* \) and every \( M^i \) for \( i \neq \ast \) form local martingales with respect to \( \bar{P} \). This is equivalent to causal validity, which means that (1) holds. \( \square \)

**Appendix D. Proof of Proposition 2**

The proof of Proposition 2 is simplified by first establishing the following lemmas.

**Lemma 1.** Consider a distribution \( P \) over \( A \cup B \) and a counting process \( N \in A \) so that \( \lambda \) is the \( \mathcal{F}^{A \cup B} \)-intensity of \( N \). If \( \lambda \) is \( \mathcal{F}^A \)-predictable, it is also the \( \mathcal{F}^A \)-intensity of \( N \).

**Proof.** Consider \( M_t := N_t - \int_0^t \lambda_s \, ds \). Now, \( \lambda \) is the \( \mathcal{F}^{A \cup B} \)-intensity of \( N \) with respect to \( P \) by assumption. By definition of the intensity \( E_P \left( \int_0^T h_s \, dM_s \right) = 0 \) for all \( \mathcal{F}^{A \cup B} \)-predictable \( h \), and in particular for every \( \mathcal{F}^A \)-predictable \( h \) as \( \mathcal{F}^A \subset \mathcal{F}^{A \cup B} \). As \( \lambda \) is \( \mathcal{F}^A \)-predictable (by
We also have (Protter, 2005, Corollary II.2) that, for \( \tilde{N} \sim \mathcal{N} \) and as \( \lambda \) is the \( \mathcal{F}^A \)-intensity of \( N \) with respect to \( P \).

**Lemma 2.** Consider joint distributions \( P \) and \( \tilde{P} \) over \( C \cup \{N^*\} \cup A \cup B \), where \( C \) is a set of counting processes, \( N^* \) a counting process and \( A \) and \( B \) are sets containing counting processes and baseline variables. Suppose that \( \tilde{P} \ll P \) and that the likelihood ratio \( W_t := d\tilde{P} \big|_{\mathcal{F}^C(N^*) \cup A \cup B} / dP \big|_{\mathcal{F}^C(N^*) \cup A \cup B} \) is given by \( W_t = \prod_{s \leq t} (\tilde{\lambda}_s^{*} / \eta_s) \Delta N_s^{*} \exp(- f^t_0 (\tilde{\lambda}_s^{*} - \eta_s) ds) \), where \( \eta \) is the \( \mathcal{F}^{C \cup \{N^*\} \cup A \cup B} \)-intensity of \( N^* \) with respect to \( P \) and \( \tilde{\lambda}^* \) is an \( \mathcal{F}^{C \cup \{N^*\}} \)-intensity of \( N^* \) with respect to \( \tilde{P} \). Suppose furthermore that the \( \mathcal{F}^{C \cup \{N^*\} \cup A \cup B} \)-intensity of every \( N \in C \) is the same under \( P \) and \( \tilde{P} \). If either

\[
C \text{ is locally independent of } B \text{ given } (C, N^*, A) \tag{20} 
\]
or

\[
N^* \text{ is locally independent of } B \text{ given } (N^*, C, A), \tag{21} 
\]

then we also have that the \( \mathcal{F}^{C \cup \{N^*\} \cup A} \)-intensity of every \( N_t \in C \) is the same under \( P \) and \( \tilde{P} \).

**Proof.** Consider \( N \in C \) with \( \mathcal{F}^{C \cup \{N^*\} \cup A} \)-intensity \( \lambda \) with respect to \( P \), and introduce \( M_t := N_t - \int_0^t \lambda_s ds \).

Assume first that (20) holds, and note that \( \lambda \) is then also the \( \mathcal{F}^{C \cup \{N^*\} \cup A \cup B} \)-intensity with respect to \( P \). Under the assumptions of the lemma we have that \( \lambda \) is the \( \mathcal{F}^{C \cup \{N^*\} \cup A \cup B} \)-intensity with respect to \( \tilde{P} \) as well. We can then appeal to Lemma 1 to conclude that \( \lambda \) is the \( \mathcal{F}^{C \cup \{N^*\} \cup A} \)-intensity of \( N \) with respect to \( \tilde{P} \).

Now, assume instead that (21) holds. We have that the likelihood ratio solves \( W_t = W_0 + \int_0^t \left( \frac{\tilde{\lambda}_s^*}{\eta_s} - 1 \right) dM_s^* \), where \( M_t^* := N_t^* - \int_0^t \eta_s ds \). Now, with (21) \( \eta \) is \( \mathcal{F}^{C \cup \{N^*\} \cup A} \)-predictable, and as \( \tilde{\lambda}^* \) is \( \mathcal{F}^{C \cup \{N^*\}} \)-predictable, \( W \) is an \( \mathcal{F}^{C \cup \{N^*\} \cup A} \)-adapted martingale with respect to \( P \). We also have (Protter, 2005, Corollary II.2) that, for \( \mathcal{F}^{C \cup \{N^*\} \cup A} \)-predictable \( h \),

\[
E_P \left( W_T \int_0^T h_s dM_s \right) = E_P \left( \int_0^T W_s h_s dM_s \right) + E_P \left( \int_0^T \int_0^T h_s dM_s dW_r \right) + E_P \left( \int_0^T h_s [M, W]_s \right) 
\]

\[
= E_P \left( \int_0^T W_s h_s dM_s \right) + E_P \left( \int_0^T \int_0^T h_s dM_s dW_r \right) + E_P \left( \int_0^T h_s W_s \left( \frac{\tilde{\lambda}_s^*}{\eta_s} - 1 \right) d[M, M^*]_s \right), 
\]
where each of the terms in the last line are zero since $M, W$ and $[M, M^*]$ are $\mathcal{F}^{\cup \{N^*\} \cup \mathcal{A}}$ adapted martingales with respect to $P$. By definition of the likelihood ratio we have $E_{\tilde{P}}\left(\int_0^T h_s dM_s\right) = E_P\left(\int_0^T h_s dM_s\right) = 0$ for every $\mathcal{F}^{\cup \{N^*\} \cup \mathcal{A}}$-predictable $h$. Thus, $M$ is an $\mathcal{F}^{\cup \{N^*\} \cup \mathcal{A}}$ adapted local martingale with respect to $\tilde{P}$ as well, which means that $\lambda$ is the $\mathcal{F}^{\cup \{N^*\} \cup \mathcal{A}}$ intensity of $N$ with respect to $\tilde{P}$. □

Proof of Proposition 2. By definition of causal validity, interventions on counting processes do not affect the distribution of baseline variables. As we will omit all the processes that are not in $\mathcal{B}_0 \cup \mathcal{N}_0$, and the intensity of $N^*$ with respect to $\tilde{P}$ by definition is determined by the intervention, it remains to show that the $\mathcal{F}^{\lambda_0}$-intensity of each $N \in \mathcal{N}^{\lambda_0}_0$ is the same under $P$ and $\tilde{P}$. To this end we will use Lemma 2 with $C = \mathcal{N}^{\lambda_0}_0$, and remove the $U_k$’s one by one. Note that, by setting $B = U_k$ and $A = \bar{U}_{k+1}$, (9) and (10) respectively imply (20) and (21) for each $k$.

We start by removing $U_1$, thus setting $B = U_1$, $A = \bar{U}^2$. Causal validity of the full model ensures that the $\mathcal{F}$-intensity of each $N \in \mathcal{N}^{\lambda_0}_0$ is the same in $P$ and $\tilde{P}$. Lemma 2 implies that the $\mathcal{F}^{\lambda_0 \setminus U_1}$-intensity of every $N \in \mathcal{N}^{\lambda_0}_0$ is the same under $P$ and $\tilde{P}$. If $K = 1$ we are done. If $K > 1$ we consider $k = 2$ and set $B = U_2$ and $A = \bar{U}^3$. Now, in the previous paragraph we concluded that the $\mathcal{F}^{\lambda_0 \setminus U_1}$-intensity of every $N \in \mathcal{N}^{\lambda_0}_0$ is the same under $P$ and $\tilde{P}$. We can thus appeal to Lemma 2 again, and infer that the $\mathcal{F}^{\lambda_0 \setminus (U_1 \cup U_2)}$-intensity of every $N \in \mathcal{N}^{\lambda_0}_0$ is the same under $P$ and $\tilde{P}$. The last argument can be repeated sequentially for $k = 3, \cdots, K$; indeed, for each $k$, the previous application of Lemma 2 gave us that the $\mathcal{F}^{\lambda_0 \setminus (U_1 \cup \cdots \cup U_{k-1})}$-intensity of each $N \in \mathcal{N}^{\lambda_0}_0$ is the same in $P$ and $\tilde{P}$. By setting $B = U_k$ and $A = \bar{U}^{k+1}$ we can use the lemma again to conclude that the $\mathcal{F}^{\lambda_0 \setminus (U_1 \cup \cdots \cup U_k)}$-intensity of each $N \in \mathcal{N}^{\lambda_0}_0$ is the same in $P$ and $\tilde{P}$. When $k = K$ we are done. □

Appendix E. Independent censoring and identifiability

We begin by showing for a general multivariate counting process that under independent censoring with respect to a subset $\mathcal{V}_0 \subset \mathcal{V} \setminus \{N^c\}$ of the whole system the $\mathcal{F}^{\lambda_0}$-intensities are identified based on the limited information (i) ignoring processes not in $\mathcal{V}_0$ and (ii) ‘stopping’ at censoring.

Right censoring implies that for all $N \in \mathcal{N}_0$ we can only ever observe the stopped processes $N_{IAC} = \int_0^s I(s \leq C) dN_s$. Note that the $\mathcal{F}^{\lambda_0}$-intensity of a counting process $N \in \mathcal{V}_0$ with
respect to $P$ defines a target parameter in the sense of (18). Under censoring, $\mathcal{F}^{V_0}$ cannot be observed, as only the information stopped at censoring can be seen. We are thus interested in whether these $\mathcal{F}^{V_0}$-intensities are identified based on the observable information. This reduced, observable information is formally denoted by the $\sigma$-algebra $\mathcal{F}^{V_0 \cup N^c}$ containing all potentially observable events for $V_0$ and stopped at censoring. Below, Lemma 3 says that independent censoring implies that the $\mathcal{F}^{V_0}$-intensity of every $N \in V_0$ is identifiable from the observable information, even if $\mathcal{F}^{V_0}$ contains unobservable events due to censoring.

**Lemma 3.** Let $\mathcal{P}$ be a local independence model where we have independent censoring in the model induced by $V_0 \cup N^c$. Whenever $N \in V_0$, there exists a non-negative and $\mathcal{F}^{V_0}$-predictable process $\mu$ such that

$$I(\cdot \leq C)\mu$$

is an $\mathcal{F}^{V_0 \cup N^c}_{t \wedge C}$-intensity for the stopped process $N_{t \wedge C}$.

If moreover $P(t \leq C|\mathcal{F}^{V_0}_t) > 0$ $P$-a.s. whenever $t < T$, then $\mu$ is an $\mathcal{F}^{V_0}_t$-intensity w.r.t. $P$ for $N$.

**Proof.** Let $\lambda$ denote the $\mathcal{F}^{V_0}$-intensity w.r.t. $P$ for $N$. Independent censoring means that $M_t := N_t - \int_0^t \lambda_s ds$ is a $P$-martingale with respect to the filtration $\mathcal{F}^{V_0 \cup N^c}$. The optional stopping theorem now implies that $I(\cdot \leq C)\lambda$ is an $\mathcal{F}^{V_0 \cup N^c}_{t \wedge C}$-intensity for the stopped process $N_{t \wedge C}$, which proves the first claim.

Suppose $\mu$ is any process such that $I(\cdot \leq C)\mu$ is an $\mathcal{F}^{V_0 \cup N^c}_{t \wedge C}$-intensity for the stopped process $N_{t \wedge C}$ and let $h$ be a bounded and $\mathcal{F}^{V_0}_t$-predictable process. Moreover, let $\lambda$ be an $\mathcal{F}^{V_0}_t$-intensity for $N$ with respect to $P$. We have that

$$E_P \left( \int_0^t h_s P(s \leq C|\mathcal{F}^{V_0}_s)(\mu_s - \lambda_s) ds \right) = \int_0^t E_P \left( h_s P(s \leq C|\mathcal{F}^{V_0}_s)(\mu_s - \lambda_s) \right) ds$$

$$= \int_0^t E_P \left( h_s I(s \leq C)(\mu_s - \lambda_s) \right) ds = E_P \left( \int_0^t h_s I(s \leq C)(\mu_s - \lambda_s) ds \right)$$

$$= E_P \left( \int_0^{t \wedge C} h_s dN_s \right) - E_P \left( \int_0^{t \wedge C} h_s dN_s \right) = 0.$$  

Since this holds for any such $h$, and $P(s \leq C|\mathcal{F}^{V_0}_t) > 0$ a.e., we have that $\mu_t = \lambda_t$ $P$-a.s. for almost every $t$. Especially, we have that $E_P \left( \int_0^T h_s dN_s \right) = E_P \left( \int_0^T h_s \mu_s ds \right)$ for every $\mathcal{F}^{V_0}_t$-predictable and bounded $h$, which proves the second claim. \[\Box\]
Remark 6. Lemma 3 says that independent censoring allows us to identify the intensities for the uncensored processes. This means that, as long as the following positivity $P(t \leq C|\mathcal{F}_t^Y) > 0$ holds $P$-a.s whenever $t < T$, there exists de-censoring maps $\zeta$ that construct $P$ restricted to $\mathcal{F}_t^Y$ from $P$ restricted to $\mathcal{F}_{t\land C}^Y \cup N^c$, since $P$ is uniquely characterised by these intensities (Jacod and Shiryaev, 2003, Theorem III 1.26). Thus, as long as the above positivity assumption holds,

$\zeta(P|_{\mathcal{F}_{T\land C}^Y \cup N^c}) = P|_{\mathcal{F}_T^Y}$. (23)

If we have a $\mu$ as in (22), it can be used for an explicit construction of the map $\zeta$ in (23) as multiplication of a likelihood; see (Jacod, 1975).

Appendix F. Proof of Proposition 3

Proof. Recall that interventions on counting processes do not affect baseline variables. We start by showing that $P$ and $\hat{P}$ are the same when restricting to $\mathcal{F} \setminus N^c$. To that end we consider a counting process $N \in \mathcal{N} \setminus \{N^c\}$ with $\mathcal{F}$-intensity $\lambda$ with respect to $P$. From causal validity $\lambda$ is also the $\mathcal{F}$-intensity of $N$ with respect to $\hat{P}$. Independent censoring means that $\text{ch}(N^c) = \emptyset$, and in particular that $\lambda$ is the $\mathcal{F} \setminus N^c$-intensity of $N$ with respect to $\hat{P}$. By appealing to Lemma 1 two times (i.e. for both $P$ and $\hat{P}$) we obtain that $\lambda$ is also the $\mathcal{F} \setminus N^c$-intensity of $N$ with respect to both $P$ and $\hat{P}$.

We conclude that $P|_{\mathcal{F} \setminus N^c} = \hat{P}|_{\mathcal{F} \setminus N^c}$. As $\mathcal{F}_T^Y \subset \mathcal{F} \setminus N^c$, this implies $P|_{\mathcal{F}_T^Y} = \hat{P}|_{\mathcal{F}_T^Y}$.

Now, pick a counting process $N \in \mathcal{V}_0$ with $\mathcal{F}_T^Y$-intensity $\tilde{\nu}$ with respect to $\hat{P}$, and let $h$ be an $\mathcal{F}_T^Y$-predictable process. Then

$$E_P\left(\int_0^T h_s dN_s\right) = E_P\left(\int_0^T h_s dN_s\right) = E_P\left(\int_0^T h_s \tilde{\nu}_s ds\right) = E_P\left(\int_0^T h_s \tilde{\nu}_s ds\right)$$

where the first and third equalities are due to $P|_{\mathcal{F}_T^Y} = \hat{P}|_{\mathcal{F}_T^Y}$ and the second by definition. Hence, $\tilde{\nu}$ is also the $\mathcal{F}_T^Y$-intensity of $N$ with respect to $P$.

Finally, the assumptions of the proposition imply that $N_0$ is locally independent of $N^c$ given $\mathcal{V}_0$, so the $\mathcal{F}_T^Y$-intensity of any $N \in \mathcal{V}_0$ is identical with its $\mathcal{F} \setminus N^c$-intensity under $P$ by definition. The analogue is true under $\hat{P}$. This implies that 1) the model restricted to $\mathcal{F} \setminus N^c$ is subject to independent censoring, and 2) the $\mathcal{F} \setminus N^c$-intensity of each $N \in \mathcal{V}_0$ is the same under $P$ and $\hat{P}$. $\square$

Proof of Corollary 4 As the model is causally valid with respect to preventing censoring, it is also causally valid with respect to randomising censoring (see Remark 5), and Proposition
ensures causal validity restricted to $\mathcal{F}_{V_0 \cup N^c}$ for both. By definition of causal validity, the $\mathcal{F}_{V_0 \cup N^c}$-intensity $\lambda$ of every $N \in V_0$ is the same after each given intervention. This means that $\lambda$ is the $\mathcal{F}_{V_0 \cup N^c}$-intensity with respect to both $P^p$ and $P^r$. As the model restricted to $\mathcal{F}_{V_0 \cup N^c}$ is subject to independent censoring (again by Proposition 3), $\lambda$ is also the $\mathcal{F}_{V_0}$-intensity with respect to both $P^p$ and $P^r$. Uniqueness of the intensities gives the desired result. □

We are now ready to prove Theorem 1, which we restate. Recall that the interventions replace the $\mathcal{F}^V$-intensities of this system by new intensities for $N^c$ and $N^x$. As we cannot observe $U$ we work with the observable intensities, where $\lambda^c$ is the $\mathcal{F}_{V_0 \cup L \cup N^c}$-intensity of $N^c$ with respect to $P$, while $\lambda^x$ denotes the $\mathcal{F}_{V_0 \cup L \cup N^c}$-intensity of $N^x$ with respect to $P$. In contrast, the interventions enforce an $\mathcal{F}_{V_0 \cup N^c}$-predictable $\tilde{\lambda}^c := \rho^c \cdot \lambda^c$, and an $\mathcal{F}_{V_0}$-predictable $\tilde{\lambda}^x := \rho^x \cdot \lambda^x$.

**Theorem 1.** With the notation and set-up as in Section E consider a local independence model $\mathcal{P}(G)$. We assume that censoring is independent with respect to $V$, i.e. $ch(N^c) = \emptyset$ in $G$. We assume causal validity with respect to an intervention that prevents censoring, and for additionally intervening on the treatment process. Let $\tilde{P}$ denote the resulting interventional model. Further, assume

(i) $N^c \not\rightarrow_G (N_0, N_L) \mid (V_0, L)$, and
(ii) $U$ is eliminable with respect to $(N^x, L \cup V_0 \setminus X)$;

finally, assume the technical conditions that $\rho^c$ and $\rho^x$ are bounded. Then we have:

The interventional distribution $\tilde{P}$ under both hypothetical interventions (preventing censoring and intervening on treatment) restricted to the subset $V_0$ is identified from the observable information $\mathcal{F}_{V_0 \cup L \cup N^c}$ by

$$\tilde{P} \big|_{V_0} = \zeta \left( \left( W_{L \cup C} \cdot P \big|_{\mathcal{F}_{V_0 \cup L \cup N^c}} \right) \bigg|_{\mathcal{F}_{V_0 \cup N^c}} \right).$$

Thus, the marginal density $\tilde{P} \big|_{V_0}$ is given by re-weighting, marginalising over $L$ and applying a de-censoring map as in (11) (see Remark 6 in Appendix E).

**Proof.** We want to identify the hypothetical distribution $\tilde{P}$ under both interventions (preventing censoring and intervening in treatment) restricted to the processes in $V_0$. We will do this by first obtaining the likelihood ratio between the observational and hypothetical distribution restricted
to the filtration $\mathcal{F}^{V_0 \cup L \cup N_c}_{T \land C}$. Here, we need to show that the weights $W_{T \land C}$ are identified given the observable information $\mathcal{F}^{V_0 \cup L \cup N_c}_{T \land C}$. This follows from the first two steps: We argue that $\mathcal{U}$ can be ‘ignored’ without destroying causal validity regarding censoring and treatment; this is based on Propositions 2 and 3 (steps 1 and 2, below). We let $\mathcal{P}^p$ correspond to the model for an intervention where censoring is prevented (no intervention on the treatment process), $\mathcal{P}^r$ corresponds to the model for an intervention where censoring is randomised according to $\hat{\lambda}^c$ (no intervention on the treatment process). Then we show that the likelihood ratio between $\hat{\mathcal{P}}$ and $\mathcal{P}$ is given by $\text{(12)}$ in (step 3, below). Finally, we argue with Lemma 3 that we can extend the measure $\hat{\mathcal{P}}$ beyond the censoring time (Step 4).

**Step 1 (marginalising $\mathcal{U}$, retaining causal validity wrt. preventing or randomising censoring):**

By Proposition 3, condition [i] ensures causal validity with respect to prevention of censoring (and hence randomisation of censoring by assumption) when restricted to $V_0 \cup L \cup \{N_c\}$; thus $\mathcal{U}$ can be ignored regarding censoring.

Moreover, with Corollary 1, we conclude that $\mathcal{P}^r$ coincides with $\mathcal{P}^p$ when restricted to $\mathcal{F}^{V_0 \cup L \cup \{N_c\}}$, and hence when restricted to $\mathcal{F}^{V_0}$ as $\mathcal{F}^{V_0} \subset \mathcal{F}^{V_0 \cup L \cup \{N_c\}}$. We can thus consider the strategy that randomises censoring, i.e. $\mathcal{P}^r$, in the remainder of the proof.

**Step 2 (marginalising $\mathcal{U}$, retaining causal validity wrt. treatment):** As censoring is independent in $\mathcal{P}(G)$ and with [i] and [iii], we have that $\mathcal{U}$ is eliminable with respect to $(N^x, L \cup \{N_c\} \cup V_0^{(x)})$, which also holds under $\mathcal{P}^r$ as no new dependencies are introduced. From Proposition 2 we thus have that the restriction of $\mathcal{P}^r$ to $V_0 \cup L \cup \{N_c\}$ (ignoring $\mathcal{U}$) remains causally valid with respect to the treatment intervention.

**Step 3 (combined intervention by using combined weights):**

In Step 1 we argued that causal validity for the intervention that randomises censoring is retained when ignoring $\mathcal{U}$. The likelihood ratio associated with this intervention is

$$\frac{d\mathcal{P}^r}{d\mathcal{P}}|_{\mathcal{F}^{V_0 \cup L \cup N_c}} = (\rho^c)^I(\tau \geq C) \exp \left(-\int_0^t (\rho^c_s - 1) \lambda^c_s ds\right).$$

Moreover, in Step 2 we argued that causal validity for the intervention on the treatment process is retained when ignoring $\mathcal{U}$. This imposes the intensity $\dot{\lambda}^x$ for the counting process $N^x$, \hspace{1cm} 40
and the likelihood ratio associated with this intervention is

\[
d\tilde{P} \bigg|_{\mathcal{F}_{V_0 \cup \mathcal{L} \cup \mathcal{N}_{C}}^{V_{t}}} \cdot dP^{r} \bigg|_{\mathcal{F}_{V_0 \cup \mathcal{L} \cup \mathcal{N}_{C}}^{V_{t}}} = \prod_{s \leq t} (\rho_{s}^{x})^{\Delta N_{s}} \exp \left( \int_{0}^{t} (\rho_{s}^{x} - 1) \lambda_{s}^{x} \, ds \right).
\]

Together, this implies that re-weighting \( P \) leads to \( \tilde{P} \), ignoring \( U \), using the following weights:

\[
d\tilde{P} \bigg|_{\mathcal{F}_{V_0 \cup \mathcal{L} \cup \mathcal{N}_{C}}^{V_{t}}} \cdot dP^{r} \bigg|_{\mathcal{F}_{V_0 \cup \mathcal{L} \cup \mathcal{N}_{C}}^{V_{t}}} = \prod_{s \leq t} (\rho_{s}^{x})^{\Delta N_{s}} \exp \left( \int_{0}^{t} (\rho_{s}^{x} - 1) \lambda_{s}^{x} \, ds \right).
\]

where \( W_{t} \) is defined as in (12). The process \( W_{t} \) is not observable after censoring. However, by the optional stopping theorem we have that

\[
(24) \quad W_{t \wedge C} \cdot P \bigg|_{\mathcal{F}_{V_0 \cup \mathcal{L} \cup \mathcal{N}_{C}}^{V_{t}}} = \tilde{P} \bigg|_{\mathcal{F}_{V_0 \cup \mathcal{L} \cup \mathcal{N}_{C}}^{V_{t}}}.
\]

Hence the stopped weights are identified by the observed information; as before we rely on the uniqueness of the intensities (Brémaud, 1981, Theorem II.T12).

**Step 4:** Now, from (24) we have \( \tilde{P} \) expressed in terms of the weights and the observational density stopped at censoring, restricted to \( \mathcal{F}_{V_0 \cup \mathcal{L} \cup \mathcal{N}_{C}}^{V_{t}} \). This means that

\[
W_{t \wedge C} \cdot P \bigg|_{\mathcal{F}_{V_0 \cup \mathcal{L} \cup \mathcal{N}_{C}}^{V_{t}}} = \tilde{P} \bigg|_{\mathcal{F}_{V_0 \cup \mathcal{L} \cup \mathcal{N}_{C}}^{V_{t}}}.
\]

Moreover, we have that independent censoring holds under \( \tilde{P} \) within \( \mathcal{V}_{0} \cup \mathcal{N}_{C} \). This is because \( \mathcal{L} \rightarrow \mathcal{N}_{C} \mid \mathcal{V}_{0} \) under \( \tilde{P} \) due to construction (as \( \tilde{\lambda}^{C} \) is \( \mathcal{F}_{V_0} \)-predictable). Thus, with the same argument as for eliminability, property (i) is retained when marginalising over \( \mathcal{L} \) so that \( \mathcal{N}_{C} \rightarrow \mathcal{N}_{0} \mid \mathcal{V}_{0} \). With Proposition 3, we see that independent censoring holds in the model restricted to \( \mathcal{V}_{0} \cup \mathcal{N}_{C} \) under \( \tilde{P} \). The de-censoring map \( \zeta \) of (23) thus yields the distribution with respect to the non-stopped filtration:

\[
\zeta \left( \left( W_{t \wedge C} \cdot P \bigg|_{\mathcal{F}_{V_0 \cup \mathcal{L} \cup \mathcal{N}_{C}}^{V_{t}}} \right) \bigg|_{\mathcal{F}_{V_0 \cup \mathcal{N}_{C}}^{V_{t}}} \right) = \zeta \left( \left( \tilde{P} \bigg|_{\mathcal{F}_{V_0 \cup \mathcal{L} \cup \mathcal{N}_{C}}^{V_{t}}} \right) \bigg|_{\mathcal{F}_{V_0 \cup \mathcal{N}_{C}}^{V_{t}}} \right) = \zeta \left( \tilde{P} \bigg|_{\mathcal{F}_{V_0 \cup \mathcal{L} \cup \mathcal{N}_{C}}^{V_{t}}} \right) = \tilde{P} \bigg|_{\mathcal{F}_{V_0 \cup \mathcal{L} \cup \mathcal{N}_{C}}^{V_{t}}}.
\]

Finally, note that the technical conditions are required so that the process (12) is uniformly integrable in order to define a proper likelihood ratio; weaker conditions can also be given (Jacod and Shiryaev, 2003, Theorem IV 4.16a). \( \square \)
