Inference from Sampling with Response Probabilities
Estimated via Calibration

Caren Hasler*

February 9, 2022

Abstract

A solution to control for nonresponse bias consists of multiplying the design weights of respondents by the inverse of estimated response probabilities to compensate for the nonrespondents. Maximum likelihood and calibration are two approaches that can be applied to obtain estimated response probabilities. The paper develops asymptotic properties of the resulting estimator when calibration is applied. A logistic regression model for the response probabilities is postulated and missing at random data is supposed. The author shows that the estimators with the response probabilities estimated via calibration are asymptotically equivalent to unbiased estimators and that a gain in efficiency is obtained when estimating the response probabilities via calibration as compared to the estimator with the true response probabilities.

Keywords: maximum likelihood estimation, nonresponse, two-phase estimation, weighting adjustment.

1 Introduction

Under complete response the Horvitz-Thompson (HT, 1952) estimator is unbiased. With nonresponse, however, this estimator is unavailable. Nonresponse can be seen as a second phase of the survey, where the mechanism that yields the nonresponse called the response mechanism is unknown (Särndal and Swensson, 1987). If the response probabilities were known, a two-phase estimator with response probabilities as inclusion probabilities of the second phase would be unbiased. Unfortunately, the response probabilities are unknown in

---

practice. A solution to control for the nonresponse bias is to postulate a model for the response probabilities, estimate these probabilities based on the postulated model, and use the estimated response probabilities in a two-phase estimator. The resulting estimator is called **two-phase Nonresponse Weighting Adjusted (NWA) estimator or empirical double expansion estimator**. Särndal and Lundström (2005) and Haziza and Beaumont (2017) provide overviews of some NWA estimators and weighting systems adjusted for nonresponse.

Two general approaches to NWA estimators are Maximum Likelihood Estimation (MLE) and calibration (Deville and Särndal, 1992). In the first approach, a model such as the logistic regression model is postulated (Cassel et al., 1983; Ekholm and Laaksonen, 1991). The parameters of the model are estimated via MLE and fitted response probabilities are obtained based on the estimated parameters. In the second approach, calibration weights are found so that the resulting NWA estimator of some auxiliary variables is equal to their population total (calibration at the population level) or to their full sample HT estimator (calibration at the full sample level). The calibration weights can be viewed as the design weights times the inverse of the estimated response probabilities. To the best of our knowledge Deville and Dupont (1993) and Dupont (1993) are the first authors to suggest the use of calibration to estimate the response probabilities. Lundström and Särndal (1999) further study point and variance estimators for both levels of calibration, population and sample.

The first approach is studied in depth in Kim and Kim (2007). The paper develops asymptotic properties of the NWA estimator under a general response model. Two main results of the paper are: 1) the NWA estimator with response probabilities estimated via MLE is asymptotically equivalent to an unbiased estimator and 2) a gain in efficiency is obtained when estimating the response probabilities via MLE as compared to the estimator with the true response probabilities. The second result was also shown by Beaumont (2005) under the logistic regression model.

In this paper, we build on Kim and Kim (2007) and develop asymptotic properties of the NWA estimator under the second approach, calibration. We postulate a logistic regression model for the response probabilities and suppose that the data is missing at random (see Rubin, 1976, for a detailed definition). We consider two levels of calibration: population and full sample (Iannacchione et al., 1991). Similarly to what Kim and Kim (2007) show for MLE, two main results are 1) the NWA estimators with the response probabilities estimated via calibration are asymptotically equivalent to unbiased estimators and 2) a gain in efficiency is obtained when estimating the response probabilities via calibration as compared to the estimator with the true response probabilities. These results are valid for both levels of calibration, population and full sample.

We also show that the NWA estimator with response probabilities estimated via cal-
ibration at the population level is generally more efficient than the NWA estimator with response probabilities estimated via calibration at the sample level, but may be associated with problems. Indeed, the optimization program may fail to find a solution to the calibration equation or may return extreme weights for some combinations of sampling designs and response mechanisms. This is less likely to happen when calibrating at the sample level. We also show that if the variable of interest is a linear combination of the auxiliary variables, the NWA estimator with response probabilities estimated via calibration at the population level, respectively full sample level, is asymptotically equivalent to the true population total, respectively full sample HT estimator.

The paper is organized as follows: Section 2 contains pieces of notation and important concepts. In Section 3, we present both approaches to response probabilities estimation. We describe some asymptotic properties of the NWA estimators of interest in Section 4 with some technical elements left in the Supplementary Material. In Sections 5 and 6 we present the variance and variance estimation of the NWA estimators of interest, respectively. We expose the results of a simulation study and highlight some pitfalls of calibration at the population level in Section 7. A discussion closes the paper in Section 8.

2 Framework

Consider a finite population \( U = \{1, 2, \ldots, i, \ldots, N\} \) of size \( N \). A vector of \( q \) auxiliary variables \( x_i = (x_{i1}, x_{i2}, \ldots, x_{iq}) \) is attached to a generic unit \( i \). We suppose that the first auxiliary variable is constant and equal to 1. The parameter of interest is the population total

\[
Y = \sum_{i \in U} y_i,
\]

for some unknown variable of interest \( y \). A sample \( s \) of size \( n \) is selected from \( U \) according to a probabilistic sampling design \( p(\cdot) \) with the aim of observing \( y_i \) for \( i \in s \). A random sample \( S \) is a random variable such that \( Pr(S = s) = p(s) \). The random sample is also defined via an indicator variable \((a_i|i \in U)^\top\) where \( a_i \) is 1 if unit \( i \) is in the sample and 0 otherwise. Consider

\[
\pi_i = Pr(i \in S) = \sum_{s \subseteq U; s \ni i} p(s),
\]

the first-order inclusion probability of unit \( i \) and suppose that \( \pi_i > 0 \) for all \( i \in U \). Let \( E_p(\cdot) \) and \( V_p(\cdot) \) denote the expectation and variance computed with respect to the sampling
design $p(\cdot)$. Under complete response, the Horvitz-Thompson (HT, 1952) estimator

$$\hat{Y} = \sum_{i \in S} \frac{y_i}{\pi_i}$$  \hfill (1)

is design-unbiased for $Y$, i.e. $E_p(\hat{Y}) = Y$.

Under nonresponse, each sampled unit $i \in S$ is classified as either respondent or non-respondent depending on whether $y_i$ is observed or missing. Consider the response indicator vector $(r_i | i \in S)^T$ where $r_i$ takes value 1 if $y_i$ is observed and 0 if it is missing and $p_i = \Pr(r_i = 1 | i \in S)$ the response probability of a sampled unit $i$. The set of respondents and nonrespondents are, respectively, $S_r = \{i \in S | r_i = 1\}$ and $S_m = \{i \in S | r_i = 0\}$. In the presence of nonresponse, the HT estimator in (1) is unavailable and the total $Y$ can be estimated via the two-phase (or double expansion) estimator

$$\hat{Y}_p = \sum_{i \in S_r} \frac{y_i}{\pi_i p_i}$$  \hfill (2)

provided that $p_i > 0$ for all $i \in S$. This estimator is unbiased since

$$E_p \left[ E_q \left( \hat{Y}_p \bigg| S \right) \right] = Y,$n

where $q(\cdot | S)$ is the probability distribution of $S_r$ given a sample $S$ and subscript $q$ indicates that the expectation is computed with respect to probability distribution $q(\cdot | S)$. The response probabilities are unknown in practice. To address this issue, a model for the response probabilities, called the response model, is postulated. The response probabilities are estimated via this model, which yields estimated response probabilities $\hat{p}_i$, and the NWA estimator (or empirical double expansion estimator)

$$\hat{Y}_{\hat{p}} = \sum_{i \in S_r} \frac{y_i}{\pi_i \hat{p}_i}$$  \hfill (3)

is used. A commonly used model for the response probabilities is the logistic regression model

$$p_i = f(x_i; \lambda) = \frac{\exp(x_i^T \lambda)}{1 + \exp(x_i^T \lambda)} = \frac{1}{1 + \exp(-x_i^T \lambda)},$$  \hfill (4)

where $\lambda$ is a parameter vector to be estimated. The response probabilities are estimated via $\hat{p}_i = f(x_i; \hat{\lambda})$ for some estimator $\hat{\lambda}$ of $\lambda$. Two available estimation methods are maximum likelihood and calibration, see Section 3.
Some required assumptions on the response mechanism are:

(R1): The data is missing at random (see Rubin, 1976, for a detailed definition). This means that

\[ Pr(i \in S_r|i \in S, x_i, y_i) = Pr(i \in S_r|i \in S, x_i). \]

(R2): The units respond independently of one another, i.e.

\[ Pr(i, j \in S_r|i, j \in S) = p_i p_j. \]

(R3): The response probabilities are bounded below, i.e. there exists a constant \( c > 0 \) so that \( p_i > c \) for all \( i \in S \).

(R4): The response probabilities are \( p_i = f(x_i, \lambda) \) as defined in (4) for some true unknown parameter vector \( \lambda \).

Assumption (R2) implies that each response indicators \( r_i \) is a draw of an independent Bernoulli trial with parameter \( p_i \). This means that \( S_r \) is selected from \( S \) via Poisson sampling design with inclusions probabilities \( p_i \).

3 Estimation

We consider two approaches to obtain the NWA estimator: MLE and calibration (Deville and Särndal, 1992). Kim and Kim (2007) study NWA estimators via MLE of the response probabilities under a general response model. For the logistic regression model, the maximum likelihood estimator of \( \lambda \) is the solution \( \hat{\lambda}_{mle} \) to the estimating equation

\[ Q_{mle}(\hat{\lambda}) = \sum_{i \in S} k_i \left[ r_i - f(x_i; \hat{\lambda}) \right] x_i = 0. \] (5)

When \( k_i = 1 \), the solution is the usual maximum likelihood estimator. When \( k_i = 1/\pi_i \), we obtain a survey weighted estimating equation. Other choices of \( k_i \) are possible. We focus on the common two aforementioned choices. An efficiency gain of the NWA estimator in (3) as compared to the two-phase estimator in (2) with true response probabilities is claimed when \( k_i = 1 \) (Beaumont, 2005; Kim and Kim, 2007). This choice yields the best estimate of \( \lambda \) and of the response probabilities. The efficiency of the NWA estimator may, however, be improved upon with \( k_i = 1/\pi_i \) for example. The study of efficiency of the two-phase estimator adjusted for nonresponse goes beyond the scope of this paper.
Two levels of calibration are possible: calibration at the population level if the population total of the auxiliary variables is known and calibration at the sample level if the full sample HT estimator of the auxiliary variables is known. The calibration estimator of $\lambda$ is the solution $\hat{\lambda}^{\text{cal},U}$ to the estimating equation

$$\sum_{i \in S_r} \frac{x_i}{\pi_i f(x_i; \hat{\lambda})} = \sum_{i \in U} x_i,$$

or equivalently

$$Q^{\text{cal},U}(\hat{\lambda}) = \sum_{i \in S_r} \frac{x_i}{\pi_i f(x_i; \hat{\lambda})} - \sum_{i \in U} x_i = 0,$$

if we calibrate at the population level. This calibration equation means that the response probabilities are chosen so that the NWA estimator of the auxiliary variables is equal to their population total. If we calibrate at the sample level, the calibration estimator of $\lambda$ is the solution $\hat{\lambda}^{\text{cal},S}$ to the estimating equation

$$\sum_{i \in S_r} \frac{x_i}{\pi_i f(x_i; \hat{\lambda})} = \sum_{i \in S} \frac{x_i}{\pi_i},$$

which is equivalent to

$$Q^{\text{cal},S}(\hat{\lambda}) = \sum_{i \in S_r} \frac{x_i}{\pi_i f(x_i; \hat{\lambda})} - \sum_{i \in S} \frac{x_i}{\pi_i} = 0.$$

Estimating Equation (7) is suggested in Iannacchione et al. (1991). It means that the response probabilities are chosen so that the NWA estimator of the auxiliary variables is equal to their full sample HT estimator.

When calibrating at the population level, the goal is to find weights, here response probabilities, so that the estimated total of some auxiliary variables matches the population total. When calibration at the sample level, the aim is to match the full sample HT estimator. Hence, the first approach attempts to correct for both the nonresponse and sampling error. The second approach attempts to only correct for the nonresponse error.

Both estimating Equations (6) and (7) can be solved using a software for calibration in the complete response case, such as function calib of R package sampling (Tillé and Matei, 2021). Indeed, noting that $1/f(x_i; \hat{\lambda}) = 1 + \exp(-x_i^T \hat{\lambda})$, these equations can be written,
respectively,

\[
\sum_{i \in S_r} \frac{\exp(-x_i^\top \hat{\lambda})}{\pi_i} x_i = \sum_{i \in U} x_i - \sum_{i \in S_r} \frac{x_i}{\pi_i},
\]

\[
\sum_{i \in S_r} \frac{\exp(-x_i^\top \hat{\lambda})}{\pi_i} x_i = \sum_{i \in S \setminus S_r} \frac{x_i}{\pi_i}.
\]

These are typical calibration equations with the raking ratio method, see Deville et al. (1993).

We compare four NWA estimators: 1) \( \hat{Y}_{mle,1} \) obtained with response probabilities estimated via Equation (5) with \( k_i = 1 \), 2) \( \hat{Y}_{mle,1/\pi} \) obtained with response probabilities estimated via Equation (5) with \( k_i = 1/\pi_i \), 3) \( \hat{Y}_{cal,U} \) obtained with response probabilities estimated via Equation (6), and 4) \( \hat{Y}_{cal,S} \) obtained with response probabilities estimated via Equation (7).

Both approaches, MLE and calibration, are here applied to estimate the response probabilities used in the NWA estimator in (3). They differ, however, in spirit and required information in the estimation process. The spirit of MLE is to maximize the likelihood that the postulated response model generated the data at hand. The focus is the estimation of the response probabilities with no explicit parameter of interest in mind. Moreover, MLE does not explicitly assume a superpopulation model, i.e. a model that links the variable of interest and the auxiliary variables. We will see in Section 4, however, that MLE assumes an implicit superpopulation model. The idea of calibration is to find response probabilities so that the NWA estimators of the auxiliary variables match their population or full sample HT estimator. Hence, the spirit is to estimate the total of some auxiliary variables as precisely as possible so that the nonresponse bias of the total of the variable of interest is as small as possible when the variable of interest and the auxiliary variables are correlated. Calibration thus focuses on a particular parameter of interest, the total, and explicitly states a superpopulation model, a linear regression model.

Both approaches also differ in the required information in the estimation process. MLE requires to know the values \( x_i \) for all sampled units \( i \in S \). Calibration at the population level via estimating Equation (6) requires to know the values \( x_i \) for all respondent units \( i \in S_r \) and the population total of \( x_i \). Calibration at the sample level via estimation Equation (7) requires to know the values \( x_i \) for all respondent units \( i \in S_r \) and the HT estimator of \( x_i \) at the sample level. For MLE and calibration at the sample level, no information is needed about the \( x_i \) out of the sample.
4 Asymptotics

In this section, we build on the results and assumptions of Kim and Kim (2007) to obtain some asymptotic properties of the NWA estimators obtained via calibration. We use the asymptotic framework of Isaki and Fuller (1982). Consider a sequence $U_N$ of embedded finite populations of size $N$ where $N$ grows to infinity. Consider a sequence of samples $s_N$ selected from $U_N$ with sampling design $p_N(\cdot)$. The first- and second-order inclusion probabilities associated with $p_N(\cdot)$ for some generic units $i$ and $j$ are $\pi_{N,i}$ and $\pi_{N,ij}$, respectively. In what follows, we will omit the subscript $N$ whenever possible to simplify notation. We consider the following common regularity conditions on the sequence of sampling designs to ensure consistent estimation of the HT estimator and its variance estimator.

(D1): As $N \to +\infty$, we have $n/N \to f \in (0, 1)$,

(D2): For all $N$, $\pi_i > \lambda_1 > 0$ for all $i \in U$,

(D3): For all $N$, $\pi_{ij} > \lambda_2 > 0$ for all $i, j \in U$,

(D4): $\limsup_{N \to +\infty} n \max_{i,j \in U, i \neq j} |\pi_{ij} - \pi_i \pi_j| < +\infty$.

From Theorem 1 of Kim and Kim (2007), we have that under the regularity conditions (D1)-(D4), Assumptions (R1)-(R4) about the response mechanism, and additional regularity conditions (P1)-(P4) stated in the Supplementary Material, the NWA estimator $\hat{Y}_{mle}$ satisfies

$$\frac{1}{N} \hat{Y}_{mle}^\text{mle} = \frac{1}{N} \hat{Y}_{\hat{p},l}^\text{mle} + O_p(n^{-1}),$$

where

$$\hat{Y}_{\hat{p},l}^\text{mle} = \sum_{i \in S} \frac{1}{\pi_i} \left[ k_i \pi_i p_i x_i^\top \gamma_n^\text{mle} + \frac{r_i}{p_i} (y_i - k_i \pi_i p_i x_i^\top \gamma_n^\text{mle}) \right],$$

$$\gamma_n^\text{mle} = \left[ \sum_{i \in S} k_i p_i (1 - p_i) x_i x_i^\top \right]^{-1} \sum_{i \in S} \frac{1 - p_i}{\pi_i} x_i y_i.$$

A similar result holds for the NWA estimators obtained via calibration Equations (6) and (7).

Result. Let the sequence of sampling designs satisfy Assumptions (D1)-(D4), the response mechanism satisfy Assumptions (R1)-(R4), and the sequence of finite populations satisfy
Assumptions (P1)-(P4) in the Supplementary Material. The NWA estimators $\widehat{Y}_{\bar{p},l}^{\text{cal},U}$ and $\widehat{Y}_{\bar{p},l}^{\text{cal},S}$ satisfy

$$\frac{1}{N} \widehat{Y}_{\bar{p},l}^{\text{cal},U} = \frac{1}{N} \widehat{Y}_{\bar{p},l} + O_p(n^{-1}),$$

$$\frac{1}{N} \widehat{Y}_{\bar{p},l}^{\text{cal},S} = \frac{1}{N} \widehat{Y}_{\bar{p},l} + O_p(n^{-1}),$$

where

$$\widehat{Y}_{\bar{p},l}^{\text{cal},U} = \sum_{i \in U} \left[ x_i^\top \gamma_n^{\text{cal},U} + \frac{a_i p_i}{\pi_i p_i} (y_i - x_i^\top \gamma_n^{\text{cal},U}) \right],$$

$$\widehat{Y}_{\bar{p},l}^{\text{cal},S} = \sum_{i \in S} \frac{1}{\pi_i} \left( x_i^\top \gamma_n^{\text{cal},S} + \frac{r_i p_i}{p_i} (y_i - x_i^\top \gamma_n^{\text{cal},S}) \right),$$

$$\gamma_n^{\text{cal},U} = \left[ \sum_{i \in U} (1 - p_i) x_i x_i^\top \right]^{-1} \sum_{i \in U} (1 - p_i) x_i y_i,$$

$$\gamma_n^{\text{cal},S} = \left( \sum_{i \in S} \frac{1 - p_i}{\pi_i} x_i x_i^\top \right)^{-1} \sum_{i \in S} \frac{1 - p_i}{\pi_i} x_i y_i.$$

The proof is given in the Supplementary Material.

**Remark 1.** A consequence of the results above is

$$\widehat{Y}_{\bar{p},l}^{\text{mle}} = \widehat{Y}_{\bar{p},l} + o_p(Nn^{-1/2}),$$

$$\widehat{Y}_{\bar{p},l}^{\text{cal},U} = \widehat{Y}_{\bar{p},l}^{\text{cal},U} + o_p(Nn^{-1/2}),$$

$$\widehat{Y}_{\bar{p},l}^{\text{cal},S} = \widehat{Y}_{\bar{p},l}^{\text{cal},S} + o_p(Nn^{-1/2}).$$

That is, each NWA estimator on the left-hand side behaves asymptotically like the linearized estimator on the right-hand side.

**Remark 2.** All three NWA estimators are asymptotically equivalent to an unbiased estimator since

$$E_p \left[ E_q \left( \widehat{Y}_{\bar{p},l} \mid S \right) \right] = E_p \left( \sum_{i \in S} \frac{y_i}{\pi_i} \right) = \sum_{i \in U} y_i,$$

for any $\widehat{Y}_{\bar{p},l} = \widehat{Y}_{\bar{p},l}^{\text{mle}}, \widehat{Y}_{\bar{p},l}^{\text{cal},U}, \widehat{Y}_{\bar{p},l}^{\text{cal},S}$. **Kim and Kim (2007)** mention this result for $\widehat{Y}_{\bar{p}}^{\text{mle}}$ on page 505.
Remark 3. If there exists a vector $\mathbf{\beta}$ such that $y_i = k_i \pi_i p_i \mathbf{x}_i^\top \mathbf{\beta}$ for all $i \in S$ then

$$\hat{Y}_{mle}^{\hat{p},l} = \sum_{i \in S} \frac{y_i}{\pi_i}.$$  

This means that $\hat{Y}_{mle}^{\hat{p}}$ is asymptotically equivalent to the full sample unknown Horvitz-Thompson estimator in this case. When estimating the response probability via MLE, see Equation (5), we implicitly assume a superpopulation model, that is $y_i$ is a linear combination of $k_i \pi_i p_i \mathbf{x}_i$. The resulting NWA estimator is such that the estimated response probabilities correct for the nonresponse error.

If there exists a vector $\mathbf{\beta}$ such that $y_i = \mathbf{x}_i^\top \mathbf{\beta}$ for all $i \in U$ then

$$\hat{Y}_{cal,U}^{\hat{p},l} = \sum_{i \in U} y_i.$$  

This means that $\hat{Y}_{cal,U}^{\hat{p}}$ is asymptotically equivalent to the unknown population total in that case. When calibrating at the population level via Equation (6), we assume a superpopulation model, that is $y_i$ is a linear combination of $\mathbf{x}_i$. The resulting NWA estimator is such that the estimated response probabilities correct for both the nonresponse and sampling error.

If there exists a vector $\mathbf{\beta}$ such that $y_i = \mathbf{x}_i^\top \mathbf{\beta}$ for all $i \in S$ then

$$\hat{Y}_{cal,S}^{\hat{p},l} = \sum_{i \in S} \frac{y_i}{\pi_i}.$$  

This means that $\hat{Y}_{cal,S}^{\hat{p}}$ is asymptotically equivalent to the full sample unknown Horvitz-Thompson estimator in this case. When calibrating at the sample level via Equation (7), we assume a superpopulation model, that is $y_i$ is a linear combination of $\mathbf{x}_i$. The resulting NWA estimator is such that the estimated response probabilities correct for the nonresponse error only.

5 Variance

Under nonresponse, we can write the variance of a generic estimator $\hat{Y}_g$ as

$$V\left(\hat{Y}_g\right) = V_{sam}\left(\hat{Y}_g\right) + V_{nr}\left(\hat{Y}_g\right),$$
where the two terms are the sampling variance and the nonresponse variance, respectively, and are given by

\[
V_{sam}(\hat{Y}_g) = V_p \left[ E_q \left( \hat{Y}_g \mid S \right) \right],
\]

\[
V_{nr}(\hat{Y}_g) = E_p \left[ V_q \left( \hat{Y}_g \mid S \right) \right].
\]

Based on this decomposition, the variance of the two-phase estimator \( \hat{Y}_p \) with the true response probabilities is given by

\[
V(\hat{Y}_p) = V_p \left( \sum_{i \in S} \frac{y_i}{\pi_i} \right) + E_p \left( \sum_{i \in S} \frac{1}{\pi_i^2} \frac{1 - p_i}{p_i} y_i^2 \right).
\]

Using the decomposition of the variance above, Kim and Kim (2007), p.507, write the variance of \( \hat{Y}_{mle}^{\hat{Y}}_{\hat{p},l} \) as

\[
V(\hat{Y}_{mle}^{\hat{Y}}_{\hat{p},l}) = V_{sam}(\hat{Y}_{mle}^{\hat{Y}}_{\hat{p},l}) + V_{nr}(\hat{Y}_{mle}^{\hat{Y}}_{\hat{p},l}),
\]

where

\[
V_{sam}(\hat{Y}_{mle}^{\hat{Y}}_{\hat{p},l}) = V_p \left( \sum_{i \in S} \frac{y_i}{\pi_i} \right),
\]

\[
V_{nr}(\hat{Y}_{mle}^{\hat{Y}}_{\hat{p},l}) = E_p \left[ \sum_{i \in S} \frac{1}{\pi_i^2} \frac{1 - p_i}{p_i} (y_i - k_i \pi_i p_i x_i^\top \gamma_{mle})^2 \right].
\]

The first term is the variance of the full sample HT estimator. The second term vanishes if there exists a vector \( \beta \) such that \( y_i = k_i \pi_i p_i x_i^\top \beta \). This agrees with Remark 3 saying that \( \hat{Y}_{mle}^{\hat{Y}}_{\hat{p},l} \) matches the full sample HT estimator when this relationship holds.

A similar decomposition holds for the NWA estimators obtained via calibration. Indeed, we can write

\[
V(\hat{Y}_{cal,U}^{\hat{Y}}_{\hat{p},l}) = V_{sam}(\hat{Y}_{cal,U}^{\hat{Y}}_{\hat{p},l}) + V_{nr}(\hat{Y}_{cal,U}^{\hat{Y}}_{\hat{p},l}),
\]

where

\[
V_{sam}(\hat{Y}_{cal,U}^{\hat{Y}}_{\hat{p},l}) = V_p \left[ \sum_{i \in S} \frac{1}{\pi_i} (y_i - x_i^\top \gamma_{cal,U}) \right],
\]

\[
V_{nr}(\hat{Y}_{cal,U}^{\hat{Y}}_{\hat{p},l}) = E_p \left[ \sum_{i \in S} \frac{1}{\pi_i^2} \frac{1 - p_i}{p_i} (y_i - x_i^\top \gamma_{cal,U})^2 \right].
\]
The first term is the variance of the full sample HT estimator of the differences $y_i - x_i^\top \gamma_{n}^{cal,U}$. Both the first and second terms vanish if there exists a vector $\beta$ such that $y_i = x_i^\top \beta$. This agrees with Remark 3 saying that $\hat{Y}_{cal,U}^{p,l}$ matches the true population total, which has zero variance, when this relationship holds.

Similarly, we can write

$$ V\left(\hat{Y}_{cal,S}^{p,l}\right) = V_{sam}\left(\hat{Y}_{cal,S}^{p,l}\right) + V_{nr}\left(\hat{Y}_{cal,S}^{p,l}\right), $$

where

$$ V_{sam}\left(\hat{Y}_{cal,S}^{p,l}\right) = V_p \left( \sum_{i \in S} \frac{y_i}{\pi_i} \right), \quad (10) $$

$$ V_{nr}\left(\hat{Y}_{cal,S}^{p,l}\right) = E_p \left[ \sum_{i \in S} \frac{1}{\pi_i} \frac{1 - p_i}{p_i} (y_i - x_i^\top \gamma_{n}^{cal,S})^2 \right]. \quad (11) $$

The first term is the variance of the full sample HT estimator. The second term vanishes if there exists a vector $\beta$ such that $y_i = x_i^\top \beta$. This agrees with Remark 3 saying that $\hat{Y}_{cal,S}^{p,l}$ matches the full sample HT estimator when this relationship holds. The decomposition of the variance of the estimators under study is summarized in Table 1.

**Table 1:** Decomposition of the variance for four estimators.

**Remark 4.** The sampling variance of the linearized estimators $\hat{Y}_{mle}^{p,l}$ and $\hat{Y}_{cal,S}^{p,l}$ is equal to the sampling variance of $\hat{Y}_p$. Their nonresponse variance is no greater than that of $\hat{Y}_p$. This means that the NWA estimators $\hat{Y}_{mle}^{p,l}$ and $\hat{Y}_{cal,S}^{p,l}$ are asymptotically equivalent to estimators that are at least as efficient as the estimator with the true response probabilities. This was shown in Kim and Kim (2007) for $\hat{Y}_{mle}^{p,l}$, see p.505. In practice, this means that for large
enough populations and samples we expect a gain in efficiency when estimating the response probabilities via MLE or calibration at the sample level as compared to using the true response probabilities.

We expect the sampling variance of the linearized estimator $\hat{Y}^{\text{cal,U}}_{\hat{p},l}$ to be smaller than the sampling variance of $\hat{Y}_p$ provided that the residuals $y_i - x_i^\top \gamma^{\text{cal,U}}_n$ have less variation than the $y_i$’s. The nonresponse variance of $\hat{Y}^{\text{cal,U}}_{\hat{p},l}$ is no greater than that of $\hat{Y}_p$. Thus, $\hat{Y}^{\text{cal,U}}_{\hat{p}}$ is asymptotically equivalent to an estimator that is at least as efficient as the estimator with the true response probabilities under the condition stated above. In practice, this means that for large enough populations and samples we expect a gain in efficiency when estimating the response probabilities via calibration at the population level as compared to using the true response probabilities provided that the residuals $y_i - x_i^\top \gamma^{\text{cal,U}}_n$ have less variation than the $y_i$’s.

**Remark 5.** Now comparing the variance of the NWA calibration estimators $\hat{Y}^{\text{cal,U}}_{\hat{p}}$ and $\hat{Y}^{\text{cal,S}}_{\hat{p}}$. We expect the sampling variance of the linearized estimator $\hat{Y}^{\text{cal,U}}_{\hat{p},l}$ to be smaller than the sampling variance of the linearized estimator $\hat{Y}^{\text{cal,S}}_{\hat{p},l}$ provided that the residuals $y_i - x_i^\top \gamma^{\text{cal,U}}_n$ have less variation than the $y_i$’s. Moreover, we expect the nonresponse variance of $\hat{Y}^{\text{cal,U}}_{\hat{p},l}$ to be close to that of $\hat{Y}^{\text{cal,S}}_{\hat{p},l}$, since the only difference is that the population coefficient $\gamma^{\text{cal,U}}_n$ in the nonresponse variance of the former is replaced by a sample estimator $\gamma^{\text{cal,S}}_n$ in the latter. In practice, this means that we expect a gain in efficiency of the NWA estimator when estimating the response probabilities via calibration at the population level as compared to the sample level, under the condition stated above.

### 6 Variance Estimation

Using the decomposition of the variance, the following estimator may be used for the variance of the NWA estimator $\hat{Y}^{\text{mle}}_{\hat{p}}$, see Kim and Kim (2007), p.507,

$$
\hat{V}(\hat{Y}^{\text{mle}}_{\hat{p}}) = \hat{V}_{\text{sam}}(\hat{Y}^{\text{mle}}_{\hat{p},l}) + \hat{V}_{\text{nr}}(\hat{Y}^{\text{mle}}_{\hat{p},l}),
$$

where

$$
\hat{V}_{\text{sam}}(\hat{Y}^{\text{mle}}_{\hat{p},l}) = \sum_{i \in S_r} \frac{1 - \pi_i \hat{y}_i^2}{\hat{p}_i} + \sum_{i,j \in S_r, i \neq j} \frac{\pi_{ij} - \pi_i \pi_j \hat{y}_i \hat{y}_j}{\pi_i \pi_j \pi_{ij} \hat{p}_i \hat{p}_j},
$$

$$
\hat{V}_{\text{nr}}(\hat{Y}^{\text{mle}}_{\hat{p},l}) = \sum_{i \in S_r} \frac{1}{\hat{p}_i^2} \left( \frac{1}{\hat{p}_i} \left( y_i - k_i \pi_i \hat{p}_i x_i^\top \gamma^{\text{mle}}_n \right)^2 \right),
$$
\[
\hat{\gamma}^{mle}_n = \left\{ \sum_{i \in S_r} k_i (1 - \hat{p}_i) x_i x_i^\top \right\}^{-1} \sum_{i \in S_r} \frac{1}{\hat{p}_i} \frac{1 - \hat{p}_i}{\hat{p}_i} x_i y_i.
\]

We consider the same approach to derive a variance estimator of NWA estimators \(\hat{Y}_{cal,U}^{\hat{p}}\) and \(\hat{Y}_{cal,S}^{\hat{p}}\). Since \(\hat{Y}_{cal,U}^{\hat{p}}\) is asymptotically equivalent to \(\hat{Y}_{cal,U}^{\hat{p},l}\), we use

\[
\hat{V} \left( \hat{Y}_{cal,U}^{\hat{p}} \right) = \hat{V}_{sam} \left( \hat{Y}_{cal,U}^{\hat{p},l} \right) + \hat{V}_{nr} \left( \hat{Y}_{cal,U}^{\hat{p},l} \right),
\]

where \(\hat{V}_{sam} \left( \hat{Y}_{cal,U}^{\hat{p},l} \right)\) and \(\hat{V}_{nr} \left( \hat{Y}_{cal,U}^{\hat{p},l} \right)\) are estimators of the variances in Equations (8) and (9), respectively. Under Assumptions (D1)-(D4),(P1), estimator

\[
\hat{V} \left( \hat{Z} \right) = \sum_{i,j \in S} \frac{\pi_{ij} - \pi_i \pi_j}{\pi_i \pi_j} \frac{z_i \pi_i}{\pi_i} \frac{z_j \pi_j}{\pi_j}
\]

is design unbiased and consistent for the variance of a full sample HT estimator \(\hat{Z} = \sum_{i \in S} \pi_i^{-1} z_i\). Based on this formula, we can estimate the sampling variance via

\[
\hat{V}_{sam} \left( \hat{Y}_{cal,U}^{\hat{p},l} \right) = \sum_{i \in S_r} \frac{1 - \pi_i}{\pi_i^2} \frac{e_i^2}{\hat{p}_i} + \sum_{i,j \in S_r:i \neq j} \frac{\pi_{ij} - \pi_i \pi_j}{\pi_i \pi_j} \frac{e_i}{\hat{p}_i} \frac{e_j}{\hat{p}_j},
\]

\[
e_i = y_i - x_i^\top \hat{\gamma}_n^{cal},
\]

\[
\hat{\gamma}_n^{cal} = \left\{ \sum_{i \in S_r} \frac{1}{\pi_i} \frac{1 - \hat{p}_i}{\hat{p}_i} x_i x_i^\top \right\}^{-1} \sum_{i \in S_r} \frac{1}{\pi_i} \frac{1 - \hat{p}_i}{\hat{p}_i} x_i y_i,
\]

where we substituted \(\hat{p}_i\) for the unknown \(p_i\). Using the same substitution, we can estimate the second term via

\[
\hat{V}_{nr} \left( \hat{Y}_{cal,U}^{\hat{p},l} \right) = \sum_{i \in S_r} \frac{1}{\pi_i^2} \frac{1 - \hat{p}_i}{\hat{p}_i} e_i^2.
\]

A similar construction for the variance of \(\hat{Y}_{cal,S}^{\hat{p}}\) yields

\[
\hat{V} \left( \hat{Y}_{cal,S}^{\hat{p}} \right) = \hat{V}_{sam} \left( \hat{Y}_{cal,S}^{\hat{p},l} \right) + \hat{V}_{nr} \left( \hat{Y}_{cal,S}^{\hat{p},l} \right),
\]

where \(\hat{V}_{sam} \left( \hat{Y}_{cal,S}^{\hat{p},l} \right)\) and \(\hat{V}_{nr} \left( \hat{Y}_{cal,S}^{\hat{p},l} \right)\) are estimators of the variances in Equations (10) and
(11), respectively. It comes

\[
\hat{V}_{\text{sam}} \left( \hat{V}_{\text{cal},S}^{p,l} \right) = \sum_{i \in S_r} \frac{1 - \pi_i y_i^2}{\hat{p}_i} + \sum_{i,j \in S_r; i \neq j} \frac{\pi_{ij} - \pi_i \pi_j}{\pi_i \pi_j \hat{p}_i \hat{p}_j} y_i y_j,
\]

\[
\hat{V}_{nr} \left( \hat{V}_{\text{cal},S}^{p,l} \right) = \sum_{i \in S_r} \frac{1}{\hat{p}_i} \left( y_i - x_i^\top \gamma_{\text{cal}}^{n} \right)^2.
\]

7 Simulation Study

7.1 Simulation Settings

Three different populations are considered and obtained as follows. We generate \( N = 1000 \) vectors \((y_i, x_{i1})^\top\) from independent and identically distributed multivariate normal distributions with mean \( \mu = (4, 4)^\top \) with three levels of correlation \( \rho = 0.6, 0.3, 0 \). The vector of auxiliary information of a unit \( i \) is \( x_i = (1, x_{i1})^\top \). For each population, a vector \( p_i \) of response probabilities is created according to the logistic regression model in Equation (4) where \( \lambda = (0.1, 0.4)^\top \). This yields a mean response rate of 84% for each of the three populations. Figure 1 shows the three populations and response probabilities as a function of the values of \( x_1 = (x_{i1}| i \in U)^\top \).

Two sampling designs are considered: 1) simple random sampling with replacement where \( n = 100 \) units are selected; 2) Poisson sampling where the inclusion probabilities are proportional to \( 1/x_1^2 \) and so that the expected number of selected units is \( n = 100 \). Ten thousand simulations are run as follows for each population and sampling design.

A sample of size (or expected size for Poisson sampling design) \( n = 100 \) is selected according to the sampling design. A set of respondents is generated with Poisson sampling design with response probabilities generated as explained above. The total \( Y \) is estimated via 7 estimators:

1. \( \hat{Y} \) (HT): the Horvitz-Thompson estimator. Note that this estimator is unavailable in practice with non-response. It serves here as a comparison point.

2. \( \hat{Y}_p \) (p): estimator with the true response probabilities in (2). This estimator is unavailable in practice. It serves here as a comparison point.

3. \( \hat{Y}_{\text{mle},1} \) (mle, 1): NWA estimator with response probabilities estimated via MLE, Equation (5), with \( k_i = 1 \).

4. \( \hat{Y}_{\text{mle},1/\pi} \) (mle, 1/\( \pi \)): NWA estimator with response probabilities estimated via MLE, Equation (5), with \( k_i = 1/\pi \).
Population 1, \( \rho = 0.6 \)  

Population 2, \( \rho = 0.3 \)  

Population 3, \( \rho = 0 \)  

Response probabilities  

**Figure 1:** Three populations with different levels of \( \rho \) and response probabilities.

5. \( \hat{Y}^{cal,U}_{\rho} \) (cal, U): NWA estimator with response probabilities estimated via calibration at the population level, Equation (6).

6. \( \hat{Y}^{cal,S}_{\rho} \) (cal, S): NWA estimator with response probabilities estimated via calibration at the sample level, Equation (7).

### 7.2 Performance of the NWA Estimators

The performance of the estimators is assessed through the following comparison measures defined for a generic estimator \( \hat{Y}_g \):
Monte Carlo relative bias (RB) defined as

$$RB = \frac{B}{Y},$$

where $B = \bar{Y}_g^{(\cdot)} - Y$, $\bar{Y}_g^{(\cdot)}$ is the mean of the estimator over the $L = 10'000$ simulations

$$\bar{Y}_g^{(\cdot)} = \frac{1}{L} \sum_{\ell=1}^{L} \hat{Y}_g^{(\ell)},$$

and $\hat{Y}_g^{(\ell)}$ is the estimator $\hat{Y}_g$ obtained at the $\ell$-th simulation.

Monte Carlo relative root variance (or relative standard deviation) defined as

$$RRVAR = \frac{(VAR)^{1/2}}{Y},$$

where

$$VAR = \frac{1}{L - 1} \sum_{\ell=1}^{L} \left( \hat{Y}_g^{(\ell)} - \bar{Y}_g^{(\cdot)} \right)^2.$$

The results are presented in Table 2. First, all four NWA estimators show a RB generally of the same order as the RB of the HT estimator and the estimator with the true response probabilities $\hat{Y}_p$. These two estimators being unbiased, this result illustrates how the four NWA estimators are nearly unbiased, see Remark 2. Second, all four NWA estimators show a smaller variance than the estimator with the true response probabilities $\hat{Y}_p$ for all populations and both sampling designs. This confirms that a gain in efficiency of the total estimator is obtained when estimating the response probabilities via MLE or calibration as compared to using the true response probabilities, see Remark 4. Third, estimator $\hat{Y}_{cal,U}$ shows the best results in terms of variance overall. The stronger the strength of the linear relationship between the variable of interest and the auxiliary variables the smaller the variance of $\hat{Y}_{cal,U}$. This is explained by the fact that when the linear relationship is strong, the variance of the residuals $y_i - x_i^T \gamma_n^{cal,U}$ is small and therefore $\hat{Y}_{cal,U}$ has a smaller variance than the other considered estimators, see Remark 4. Last, a choice between $k_i = 1$ and $k_i = 1/\pi_i$ in MLE is not clear based on these results. For simple random sampling, both options yield equal performance. This was expected since all $1/\pi_i$ are equal with this sampling design. For Poisson sampling design, the estimator with $k_i = 1/\pi_i$ has lower variance but higher bias than the estimator with $k_i = 1$.

7.3 Performance of the Variance Estimators

The variance of the four NWA estimators is estimated for each simulation run with the formulae of Section 6. The performance of the variance estimators is assessed through the following comparison measures defined for a generic estimator \(\hat{Y}_g\):

- Monte Carlo relative bias (RB) defined as

  \[
  RB = \frac{B}{V_{\text{sim}}(\hat{Y}_g)},
  \]

  where \(V_{\text{sim}}(\hat{Y}_g)\) is the variance of \(\hat{Y}_g\) over the \(L = 10'000\) simulations, \(B = \hat{V}(\hat{Y}_g^{(i)}) - \hat{Y}_g \).
\[ V_{\text{sim}}(\hat{Y}_g), \text{ and } \hat{V}(\hat{Y}_g^{(i)}) \] is the mean of \( \hat{V}(\hat{Y}_g) \) over the \( L = 10'000 \) simulations,

- Mean length of the 95% confidence interval (CI) based on the normal distribution

\[ 95\% \text{CI} = \left[ \hat{Y}_g - 1.96\sqrt{\hat{V}(\hat{Y}_g)}; \hat{Y}_g + 1.96\sqrt{\hat{V}(\hat{Y}_g)} \right] \]

over the \( L = 10'000 \) simulations,

- CR: the actual coverage rate of the 95% CI, i.e. the proportion of times the 95% CI contains the true total \( Y \).

The results are presented in Table 3. For simple random sampling, all four estimators yield comparable results in Population 1, with low RB and CR close or equal to the nominal coverage rate of 95%. For the other two populations, when the correlation is weaker, all NWA estimators underestimate the variance (RB is negative) and yield a CR between 88% and 93%. For Poisson sampling, the estimator of the variance of \( \hat{Y}_{\text{cal,U}}^\hat{p} \) underestimates the variance, while the other three estimators overestimate it. The length of the CI is much less with this estimator than with the other three and the CR tends to be slightly less. This means that estimator \( \hat{Y}_{\text{cal,U}}^\hat{p} \) is preferred if we want a narrower CI with a CR slightly lower than the nominal coverage of 95%, and the other three are preferred if we want a CR close to the nominal coverage of 95%. The performance of all four estimators is therefore comparable. Overall, all variance estimators perform quite well for all three populations and both sampling designs.

### 7.4 Cautions with Calibration at the Population Level

When estimating the response probabilities via calibration at the population level, we attempt to correct both the sampling and nonresponse error. This may seem attractive but there are two main pitfalls highlighted in the simulation study: 1) convergence problems and 2) extreme weights. First, depending on the sampling design and nonresponse mechanism, it may happen that the optimization program fails to converge to a solution to the estimating equations. In the simulations, it only happened when calibrating at the population and with Poisson sampling in 2 to 3% of the simulations in all three populations. These figures may change if we change convergence tolerances. Second, it may happen that the optimizer returns final weights \( 1/(\pi_i \hat{p}_i) \) very large compared to other weights or to the true unobservable weights \( 1/(\pi_i p_i) \). Table 4 shows the maximum final weights across all simulations. The maximum final weights are all close to one another and to the true unobservable weights.
Table 3: Relative bias (RB) of the variance estimator, mean length of the 95% confidence interval, and actual coverage of this interval for four NWA estimators.

</table>

The two aforementioned pitfalls share a common reason. When estimating the response probabilities via MLE or calibration at the sample level, the estimating equation is based on the full sample only, see Equations (5) and (7). This means that these methods attempt to correct the nonresponse error. When estimating the response probabilities via calibration at the population level, however, the estimating equation is based on the population, see Equation (6). The goal is to modify the weights of the respondents units so that the NWA estimator of the auxiliary variables is equal to their population total. This means that this method attempts to correct both the sampling and nonresponse error. In some cases, this may be problematic. For instance, in the case of Poisson sampling above, the inclusion probabilities are inversely proportional to \(x_1^2\). As a result, it is likely to obtain a sample and a set of respondents with no or very few units with large values of \(x_1\). It may be impossible to increase the weights of the respondents that tend to have smaller values of \(x_1\), so that

the large values of the unsampled or nonrespondents units are compensated to obtain the population total. In this case the optimizer does not converge to a solution, or the few respondents units with large values are given extreme weights to compensate.

A typical case in which we could encounter such problems is any combination of sampling design and nonresponse mechanism that generates respondents sets with none or very few of the units with the large values of the auxiliary variables. Note that the large weights associated with calibration at the population level does not seem to cause problems in terms of total estimation. The results of the simulations suggest that the performance of the NWA estimator with large weights (with response probabilities estimated via calibration at the population level) is as good as that of the other NWA estimators overall. However, it may become problematic if the obtained weights are applied for another purpose, such as estimating another parameter of interest or some parameters in domains. The two aforementioned problems may happen with calibration at the sample level or MLE but to a lesser extent. It did not happen with the presented simulation settings.
8 Discussion

We build on Kim and Kim (2007) and develop asymptotic properties of the NWA estimator when calibration is applied to estimate the response probabilities. We postulate a logistic regression model for the response probabilities. We consider two levels of calibration: population and full sample. The main results are 1) the NWA estimators with the response probabilities estimated via calibration are asymptotically equivalent to unbiased estimators, 2) a gain in efficiency is obtained when estimating the response probabilities via calibration as compared to the estimator with the true response probabilities, 3) the NWA estimator with the response probabilities estimated via calibration at the population level is generally more efficient than the NWA estimator with response probabilities estimated via calibration at the sample level, 4) the optimization program may fail to find a solution to the calibration equation or may return extreme weights for some combinations of sampling designs and response mechanisms. This is more likely to happen when calibrating at the population level. The paper studies and compares NWA estimators obtained either via MLE or calibration. Some authors suggest to first estimate the response probabilities via MLE in order to bypass the problem of extreme weights and then calibrate to further improve the efficiency of the NWA estimator, see Haziza and Beaumont (2017), p.222. This goes beyond the scope of this research and is the subject of future work.

Inference from Sampling with Response Probabilities
Estimated via Calibration
Supplementary Material

The following assumptions about the sequence of finite populations are needed for the proof of the Result.

(P1): The study variable \( y_i \) has bounded second and forth moments, and \( x_i x_i^\top y_i \) is bounded, i.e.

\[
\limsup_{N \to +\infty} \frac{1}{N} \sum_{i \in U} u_i < +\infty,
\]

where \( u_i \) is any of \( y_i^2, y_i^4, x_i x_i^\top y_i \).

(P2): The sample moments of \( x_i y_i \) and \( x_i x_i^\top y_i \) converge to their population moments

\[
\frac{1}{N} \sum_{i \in S} \frac{v_i}{\pi_i} - \frac{1}{N} \sum_{i \in U} v_i = O_p(n^{-1/2}),
\]

where \( v_i \) is any of \( x_i y_i \) or \( x_i x_i^\top y_i \).

(P3): The respondents moments of \( x_i y_i \) and \( x_i x_i^\top y_i \) converge to their sample moments

\[
\frac{1}{N} \sum_{i \in S_r} \frac{v_i}{\pi_ip_i} - \frac{1}{N} \sum_{i \in S} \frac{v_i}{\pi_i} = O_p(n^{-1/2}),
\]

where \( v_i \) is defined above.

(P4): The estimators \( \tilde{\lambda}^{cal,U} \) and \( \tilde{\lambda}^{cal,S} \) satisfy

\[
\tilde{\lambda}^{cal,U} - \lambda^0 = \left\{ \mathbb{E}_p \mathbb{E}_q \left[ \frac{\partial}{\partial \lambda} Q^{cal,U}(\lambda^0) \bigg| S \right] \right\}^{-1} Q^{cal,U}(\lambda^0) + o_p(n^{-1/2}),
\]

\[
\tilde{\lambda}^{cal,S} - \lambda^0 = \left\{ \mathbb{E}_q \left[ \frac{\partial}{\partial \lambda} Q^{cal,S}(\lambda^0) \bigg| S \right] \right\}^{-1} Q^{cal,S}(\lambda^0) + o_p(n^{-1/2}).
\]

Proof of the Result. The first part of the proof is similar to the first part of the proof of Theorem 1 of Kim and Kim (2007). The second part, from Equation (S7), is specific to the
NWA estimators obtained via calibration. We have

\[ \hat{p}_i^{-1} = p(x_i; \lambda) - 1 + \left( \frac{\partial p(x_i; \lambda)}{\partial \lambda} \right)^{-1} \bigg|_{\lambda = \lambda^0} \left( \hat{\lambda}^{cal,U} - \lambda^0 \right) \]

\[ + \frac{1}{2} \left( \hat{\lambda}^{cal,U} - \lambda^0 \right)^{\top} \left( \frac{\partial^2 p(x_i; \lambda)}{\partial \lambda \partial \lambda^{\top}} \right)^{-1} \bigg|_{\lambda = \tilde{\lambda}} \left( \hat{\lambda}^{cal,U} - \lambda^0 \right), \]

where \( \tilde{\lambda} \) is on the line segment between \( \hat{\lambda}^{cal,U} \) and \( \lambda^0 \). The NWA estimator \( \hat{Y}_{\hat{p},l}^{cal,U} \) can be written as

\[ \frac{1}{N} \hat{Y}_{\hat{p},l}^{cal,U} = \frac{1}{N} \sum_{i \in S} \frac{r_i}{\pi_i} p_i y_i + A_N \left( \hat{\lambda}^{cal,U} - \lambda^0 \right) \]

\[ + \frac{1}{2} \left( \hat{\lambda}^{cal,U} - \lambda^0 \right)^{\top} B_N \left( \hat{\lambda}^{cal,U} - \lambda^0 \right), \quad \text{(S3)} \]

where

\[ A_N = \frac{1}{N} \sum_{i \in S} \frac{r_i}{\pi_i} p_i \left( \frac{\partial p(x_i; \lambda)}{\partial \lambda} \right)^{-1} \bigg|_{\lambda = \lambda^0} y_i, \]

\[ B_N = \frac{1}{N} \sum_{i \in S} \frac{r_i}{\pi_i} \left( \frac{\partial^2 p(x_i; \lambda)}{\partial \lambda \partial \lambda^{\top}} \right)^{-1} \bigg|_{\lambda = \tilde{\lambda}} y_i. \]

In our case

\[ p(x_i; \lambda)^{-1} = 1 + \exp \left( -x_i^{\top} \lambda \right), \]

\[ \frac{\partial p(x_i; \lambda)^{-1}}{\partial \lambda} = (1 - p(x_i; \lambda)) x_i, \]

\[ \frac{\partial^2 p(x_i; \lambda)^{-1}}{\partial \lambda \partial \lambda^{\top}} = p(x_i; \lambda)^{-1} (1 - p(x_i; \lambda)) x_i x_i^{\top}. \]

We obtain

\[ A_N = \frac{1}{N} \sum_{i \in S} \frac{r_i}{\pi_i} \frac{p_i - 1}{p_i} x_i y_i, \]

\[ B_N = \frac{1}{N} \sum_{i \in S} \frac{r_i}{\pi_i} \frac{1 - p_i}{p_i} x_i x_i^{\top} y_i. \]

From assumption (P3), we have

\[ A_N = \frac{1}{N} \sum_{i \in S} \frac{p_i - 1}{\pi_i} x_i y_i + O_p(n^{-1/2}), \quad \text{(S4)} \]
and from assumption (P2) we obtain
\[ A_N = \frac{1}{N} \sum_{i \in U} (p_i - 1)x_iy_i + O_p(n^{-1/2}). \] (S5)

From Assumptions (P1), (P2), and (P3), we have
\[ B_N = O_p(1). \] (S6)

From Equation (S1), it comes
\[ \hat{\lambda}^{\text{cal,U}} - \lambda^0 = \left[ \sum_{i \in U} (1 - p_i)x_i x_i^\top \right]^{-1} \sum_{i \in U} \left( \frac{a_i r_i}{\pi_i p_i} - 1 \right) x_i + o_p(n^{-1/2}). \] (S7)

Inserting Equations (S5), (S6), and (S7) into Equation (S3) yields
\[ \frac{1}{N} \hat{Y}^{\text{cal,U}}_{\bar{p},l} = \frac{1}{N} \sum_{i \in U} \left[ x_i^\top \gamma_n^{\text{cal,U}} + \frac{a_i r_i}{\pi_i p_i} y_i - x_i^\top \gamma_n^{\text{cal,U}} \right] + O_p(n^{-1}), \]

where
\[ \gamma_n^{\text{cal,U}} = \left[ \sum_{i \in U} (1 - p_i)x_i x_i^\top \right]^{-1} \sum_{i \in U} (1 - p_i)x_i y_i. \]

A similar construction for \( \hat{Y}^{\text{cal,S}}_{\bar{p},l} \) yields
\[ \frac{1}{N} \hat{Y}^{\text{cal,S}}_{\bar{p}} = \frac{1}{N} \sum_{i \in S} \frac{1}{\pi_i p_i} y_i + A_N^\top \left( \hat{\lambda}^{\text{cal,S}} - \lambda^0 \right) + \frac{1}{2} \left( \hat{\lambda}^{\text{cal,S}} - \lambda^0 \right)^\top B_N \left( \hat{\lambda}^{\text{cal,S}} - \lambda^0 \right), \] (S8)

where \( A_N \) and \( B_N \) are as above. From Equation (S2) it comes
\[ \hat{\lambda}^{\text{cal,S}} - \lambda^0 = \left( \sum_{i \in S} \frac{1 - p_i}{\pi_i} x_i x_i^\top \right)^{-1} \sum_{i \in U} \left( \frac{a_i r_i}{\pi_i p_i} - 1 \right) x_i + o_p(n^{-1/2}). \] (S9)
Inserting Equations (S4), (S6), and (S9) into Equation (S8) yields

\[
\frac{1}{N} \hat{\gamma}_{\text{cal}, S}^{p,l} = \frac{1}{N} \sum_{i \in S} \frac{1}{\pi_i} \left[ x_i^\top \gamma_{n}^{\text{cal}, S} + \frac{r_i}{p_i} (y_i - x_i^\top \gamma_{n}^{\text{cal}, S}) \right] + O_p(n^{-1}),
\]

where

\[
\gamma_{n}^{\text{cal}, S} = \left( \sum_{i \in S} \frac{1 - p_i}{\pi_i} x_i x_i^\top \right)^{-1} \sum_{i \in S} \frac{1 - p_i}{\pi_i} x_i y_i.
\]
