Transfer-Learning Across Datasets with Different Input Dimensions: An Algorithm and Analysis for the Linear Regression Case

Luis Pedro Silvestrin 1  Harry van Zanten 2  Mark Hoogendoorn 1  Ger Koole 2

Abstract
With the development of new sensors and monitoring devices, more sources of data become available to be used as inputs for machine learning models. These can on the one hand help to improve the accuracy of a model. On the other hand however, combining these new inputs with historical data remains a challenge that has not yet been studied in enough detail. In this work, we propose a transfer-learning algorithm that combines the new and the historical data, that is especially beneficial when the new data is scarce. We focus the approach on the linear regression case, which allows us to conduct a rigorous theoretical study on the benefits of the approach. We show that our approach is robust against negative transfer-learning, and we confirm this result empirically with real and simulated data.

1. Introduction
The constant evolution of sensor technology and measuring equipment brings ever more data sources that can be employed by machine learning practitioners to build better predictive models. In the healthcare domain, for example, new ICT equipment is installed and starts generating new sensory data that helps doctors to make better diagnostics (Sheng & Ling, 2006). Similarly, in the predictive maintenance domain, new sensors are developed and installed to help monitoring the state of industrial equipment. In both cases, it is desirable to update the predictive model or to train a new one so that it can make use of the new inputs. However, the data collection can be expensive and time-consuming, in a way that the amount of data samples with the new input can be sparse so that training a new model with it is infeasible. This can be seen as a transfer-learning problem where there are two datasets: the historical data with plenty of samples but without the new input features and the newly collected data with fewer samples, but with all available input features. The goal then is to use the historical data as the source dataset to improve the prediction accuracy using all inputs, which are observed only in the target dataset. We refer to this setup as "incremental input transfer-learning".

Research in transfer-learning and domain adaptation has put forward methods for learning a target task with limited data available by using data from other similar tasks referred to as source tasks. For example, recent transfer-learning works (WEI et al., 2018) yield state-of-the-art accuracy on classifying images from a target domain given only a small portion of target data. These works have considered mainly two variations of this setting: transfer across different tasks and transfer across different input domains (Pan & Yang, 2010). For the latter case, most research works assume that the inputs have the same dimension and come from different distributions, exploiting some semantic similarity between the domains (Chen et al., 2021; 2015; Obst et al., 2021; Mousavi Kalan et al., 2020). Although these works assume arbitrary distributions for source and target domains, it is non-trivial to show that their results generalize when the input dimensions are different. Other works use mapping functions to cast the data into a new domain where the source and target data are compatible, but we argue that for the incremental input case there should be a simpler method for combining both datasets since the similarity between domains is high. On top of that, to the best of our knowledge, this type of transfer-learning has not been studied yet.

In this paper, we study the incremental input problem theoretically in its linear regression version. We summarize our contributions in the three following items:

- We provide an efficient and easy to implement transfer-learning approach for this problem which is especially helpful when the new input data is scarce;
- We show through rigorous theoretical study that the approach is robust against negative transfer-learning, regardless of the amount of source and target samples, and we prove an upper bound for its generalization error at the same time;

2. Related Work

Domain Adaptation: In domain adaptation, one is concerned with the problem of learning a task in one input domain with limited data by using numerous data from different input domains. Seminal work by Ben-David et al. (2010) studies the theoretical error bounds of a classifier trained from both source and target domain simultaneously by using a convex sum of the errors in both domains. Chen et al. (2021) proposes a mapping for the source and target inputs to a new representation which can then be used for domain adaptation regression. These works are fundamentally different from ours as they do not consider the possibility that the source and target domains differ by a known subset of the input features, or they do not use the target labels in the learning process (Sun et al., 2016; Zhao et al., 2018).

Transfer-Learning: Studies in transfer-learning comprise broader topics than domain adaptation, as it can include algorithms to transfer not only across different input domains but also different tasks (Pan & Yang, 2010). In the linear regression case, Obst et al. (2021) propose the notion of transfer gain and statistical test to tell when using a source dataset to pre-train a model is better than training a model from scratch. They assume that the model should be fine-tuned by using gradient descent on the target data, but often this approach is less efficient than the least-squares method since it requires carefully selecting the step size and number of iterations, and can lead to sub-optimal solutions. Chen et al. (2015) present a linear regression method that combines two datasets: a small and unbiased one and another one large but biased. They study in detail the conditions when their approach is beneficial as a function of the amount of bias in the large dataset. Their setting differs from ours mainly because we assume that one or more variables are not observed in the large dataset, while they assume that all variables are present in both datasets. Mousavi Kalan et al. (2020) show the minimax bounds for transfer-learning in the linear regression setting based on a notion of true distributions where the source and target datasets are sampled from. They introduce three classes of problems according to the distance between the distributions where the larger the distance, the higher is the lower bound on the generalization error of the transfer-learning algorithm. Hanneke & Kpotufe (2019) propose a new discrepancy metric between source and target data and prove the minimax bounds for learning a classifier according to their metric.

Incremental attribute learning: The problem of learning a model when the number of inputs is changing has been studied previously by Guan & Li (2001). They propose an algorithm to automatically update a neural network when new inputs are discovered. However, as their work’s main focus is to propose a new algorithm and evaluate it empirically, there is no study about its theoretical properties. In addition, they assume sufficient data to train a neural network from scratch using the new features, which may, in many cases, mean that the historical data is no longer necessary.

Missing data: Another way of approaching the incremental learning problem is by treating the new features as missing in the source dataset and solving it by using missing data techniques, widely documented by Little & Rubin (2019). A classic work in this domain studies the expectation maximization algorithm to estimate the linear regression parameters from incomplete datasets (Dempster et al., 1977), but we argue that with the transfer-learning perspective we are able to derive a faster and simpler algorithm to make the best use of the incomplete data.

3. Defining a linear model for the source and the target datasets

We are concerned with the problem of learning a model based on two datasets: the historical data and the newly collected data containing extra features. We will refer to the first one as the target dataset and to the second one as the source dataset since we want to tackle this problem using a transfer-learning approach. We choose linear regression for this study because it allows us to derive closed-form solutions that are easier to inspect and gain insights into the nature of the problem. The labels in both datasets represent the same linear regression task and follow the same prior distribution. In this section, want to give a formal definition of these datasets and their conditional distributions assuming the context of linear regression. These definitions will be used throughout the remainder of the paper.

We define the target dataset as \((x_T, Y_T)\), where \(x_T \in \mathbb{R}^{n_T \times d_T}\) is a full rank design matrix containing \(n_T\) independent observations of \(d_T\) input features and \(Y_T \in \mathbb{R}^{n_T}\) is a random vector containing the respective labels. They are related by the linear model \(Y_T = x_T \theta + w_T\), where \(\theta\) is the \(d_T\)-dimensional parameter vector describing the linear relationship between inputs and labels, and \(w_T \sim \mathcal{N}(0, \sigma^2 I_{n_T})\) is additive Gaussian noise. Our goal is to learn the parameter vector \(\theta\). In addition, we define the source dataset as \((x_S, Y_S)\), where \(x_S \in \mathbb{R}^{n_S \times d_S}\) is a full rank matrix containing \(n_S\) observations of \(d_S\) input features \((d_S < d_T)\) and \(Y_S \in \mathbb{R}^{n_S}\) represents the random vector of the labels. For this dataset, we assume that the relationship between the labels and inputs is \(Y_S = x_S \theta' + X'' \theta'' + \epsilon_S\), where \(\theta'\) and \(\theta''\) correspond respectively to the first \(d_S\) and last \(d_T - d_S\) components of \(\theta\) and \(X''\) is a \(n_S \times (d_T - d_S)\) random matrix with indepen-
we want to define a transfer-learning approach that combines the transfer-learning approach that we introduce in the previous sections. In the end, we put all these findings together into a data-pooling estimator. We also study some properties of this solution and deriving its solution which leads to our data-pooling estimator. Based on the previously defined source and target datasets, we define our data-pooling loss \( R_\alpha(\theta) \) as the weighted sum of the losses over the source and the target datasets (respectively \( R_S \) and \( R_T \)), where \( \alpha = (\alpha_S, \alpha_T) \) is the vector of positive weights:

\[
R_\alpha(\theta) = \alpha_S R_S(\theta) + \alpha_T R_T(\theta)
\]

Intuitively, when \( \alpha_T \gg \alpha_S \), the error in the target dataset is scaled by a factor larger than the error in the source dataset and the solution obtained by optimizing \( R_\alpha \) will be closer to the basic estimator. On the other hand, when \( \alpha_T \ll \alpha_S \), then \( R_S \) will dominate the loss, and the optimal solution will distillate from the basic estimator.

In the incremental input case, we need to make sure that the parameters related to the new inputs will not influence the error calculated on the source dataset. To achieve that, we define \( R_S(\theta) = \|Y_S - x_S\tilde{1}\tilde{\theta}\|^2 \), where \( \tilde{1} \) describes a \( d_T \times d_S \) matrix such that \( \tilde{l}_{ii} = 1 \) and \( \tilde{l}_{ij} = 0 \) when \( i \neq j \). In practice, \( x_S\tilde{1}^\top \) can be interpreted as filling up the missing dimensions of \( x_S \) with zeros. By replacing the definitions of \( R_S \) and \( R_T \) in Equation 2 we obtain:

\[
R_\alpha(\theta) = \alpha_S \|Y_S - x_S\tilde{1}\tilde{\theta}\|^2 + \alpha_T \|Y_T - x_T\theta\|^2
\]

**Proposition 4.1.** Given a source and a target dataset as defined in Section 3 and independent from each other, the data-pooling loss \( R_\alpha(\theta) \) is convex for any choice of \( \alpha_S, \alpha_T \in \mathbb{R}^+ \). Therefore it has a unique minimizing solution which is defined by:

\[
\hat{\theta}_\alpha = (\alpha_S\tilde{I}_S \tilde{1}_S x_S^\top + \alpha_T x_T^\top x_T)^{-1} \left( \alpha_S\tilde{I}_S \tilde{1}_S Y_S + \alpha_T x_T^\top Y_T \right)
\]

The result of proposition Proposition 4.1 (proved in the supplemental material) gives a direct form of computing the data-pooling estimator \( \hat{\theta}_\alpha \) and an analytical formula which can also be used for further analysis. Based on it, and the known distributions of \( Y_T \) and \( Y_S \), we are able to derive closed forms of the expected value and the variance of \( \hat{\theta}_\alpha \).

**Proposition 4.2.** The data-pooling estimator is an unbiased estimator of \( \theta \) (proof in the supplemental material). Its expected value and variance are:

\[
E[\hat{\theta}_\alpha] = \theta
\]

\[
\text{Var}(\hat{\theta}_\alpha) = M^{-1}(\alpha_S^2 \sigma_S^2 \Sigma_S \tilde{I}_S + \alpha_T^2 \sigma_T^2 \Sigma_T)M^{-1}
\]

where \( \Sigma_S = x_S^\top x_S \), \( \Sigma_T = x_T^\top x_T \) and \( M = \alpha_S \Sigma_S \tilde{I}_S + \alpha_T \Sigma_T \).
The fact that \( \hat{\theta}_\alpha \) is unbiased guarantees that it converges to the real parameters \( \theta \), regardless of the choice of \( \alpha \). Its variance, however, is influenced by \( \alpha \), so we are interested in selecting the hyperparameter \( \alpha \) in a way that the variance is minimal. The relationship between \( \alpha \) and \( \text{Var}(\hat{\theta}_\alpha) \) is complex, as Equation 6 shows, so choosing it is not trivial.

### 4.2. The relationship of data-pooling and maximum likelihood

A natural way of estimating \( \theta \) is by maximizing the likelihood of the source and target labels and observations given that we know their probability distributions and also the distribution of the unobserved features \( X'' \). By looking at the negative log-likelihood function of the labels \( Y_S \) and \( Y_T \) given the observations \( x_T \) and \( x_S \), we arrive at the following equation:

\[
\mathcal{L} = \frac{1}{2\sigma_S^2} \| Y_S - x_S \theta' \|^2 + \frac{1}{2\sigma_T^2} \| Y_T - x_T \theta \|^2 + \frac{n_S}{2} \log(\sigma_S^2) + \frac{n_T}{2} \log(2\pi) + \frac{n_T}{2} \log(\sigma_T^2) \tag{7}
\]

Finding the maximum likelihood estimator (MLE) of \( \theta \) by minimizing the equation above is a complex non-linear problem. We observe that if we take the data-pooling loss \( \mathcal{R}_\alpha \) with \( \alpha_T = \frac{1}{\sigma_T^2} \) and \( \alpha_S = \frac{1}{\sigma_S^2} \), then we can rewrite Equation 7 as:

\[
\mathcal{L} = \frac{1}{2} \mathcal{R}_\alpha(\theta) + \frac{n_S}{2} \log(\sigma_S^2) + \frac{n_S + n_T}{2} \log(2\pi) + \frac{n_T}{2} \log(\sigma_T^2) \tag{8}
\]

This means that, in this case, the data-pooling approach is a reasonable way to approximate the MLE of \( \theta \) by minimizing a simpler criterion. It suggests that \( \alpha_T = \frac{1}{\sigma_T^2} \) and \( \alpha_S = \frac{1}{\sigma_S^2} \) might be an optimal choice for the hyperparameter \( \alpha \).

### 4.3. The data-pooling algorithm

From a practical point of view, the data-pooling estimator cannot be computed directly since it depends on variables that in reality are unknown, namely \( \sigma_S^2 \) and \( \sigma_T^2 \). Nevertheless, in order to apply it in practice, these variables can be estimated separately as \( \hat{\sigma}_S^2 = \| y_S - x_S \hat{\theta}_S \|^2/(n_S - d_S) \) and \( \hat{\sigma}_T^2 = \| y_T - x_T \hat{\theta}_T \|^2/(n_T - d_T) \). Another practical impairment for the result above is that it relies on the assumption that the new features follow a normal distribution with zero mean (\( \mathbb{E}[X''] = 0 \)). This is especially important for the data-pooling loss in Equation 3, where we fill up the lacking observations in the source dataset with zeros (\( x_S \mathbb{I}^\top \)). We approach this issue by shifting the observations of the new features in the target data by their estimated mean. It is important to notice that by using this trick, we are also changing the resulting estimate of the bias \( \theta_0 \). It means that, after computing the data-pooling estimator, to use it for predictions on new data, it is necessary to apply the same shift to that data. To sum up all these steps, we describe the algorithm to compute \( \hat{\theta}_\alpha \) from the observations of source and target data in Algorithm 1.

In short, the data-pooling approach is a simple and computationally cheap way of approximating the maximum likelihood estimator of \( \theta \) by combining historical data and new observations. In the following section, we want to study the benefit of using the source dataset by comparing our approach to the basic estimator.

### 5. Transfer gain of data-pooling

The transfer gain is a measure defined in (Obst et al., 2021) to assess whether a transfer-learning model which uses both the target and the source datasets performs better than the basic estimator which uses only the target dataset. It is measured as the difference between the generalization error of the basic estimator and that of the transfer-learning approach based on a new unseen data point from the target distribution.

Suppose we get a new row vector \( x \) containing \( d_T \) features. According to the definition of the target data, the corresponding label \( Y \) is distributed as \( Y = x \theta + w \), where \( w \sim \mathcal{N}(0, \sigma^2) \) is independent from everything else. If we have an estimator \( \hat{\theta} \) then we can predict the new label as \( x \hat{\theta} \). The generalization error is then given by \( \mathbb{E}[(Y - x \hat{\theta})^2] \). In this work, we define the transfer gain in terms of the data-pooling estimator with weight \( \alpha \) as:

\[
G(x) = \mathbb{E}[(Y - x \hat{\theta}_T)^2] - \mathbb{E}[(Y - x \hat{\theta}_\alpha)^2] \tag{9}
\]

Intuitively, a positive transfer gain indicates that using the source dataset improves the predictions in new unseen data from the target distribution. If it is negative, then it means that either the source data is not helpful or that the transfer-learning approach is sub-optimal.

**Proposition 5.1.** Since both \( \hat{\theta}_T \) and \( \hat{\theta}_\alpha \) are unbiased estimators of \( \theta \), then the transfer gain can be rewritten in terms
of the difference of their variances (proof in supplemental material):

\[ G(x) = x(\text{Var}(\hat{\theta}_T) - \text{Var}(\hat{\theta}_o))x^\top \]  

(10)

Furthermore, by replacing the variances of \( \hat{\theta}_T \) and \( \hat{\theta}_o \) in equation (10), it becomes:

\[ G(x) = x[\sigma^2\Sigma_T^{-1} - M^{-1}(\sigma^2\alpha^2_S\Sigma_S^2\Sigma + \sigma^2\alpha^2_T\Sigma_T)]M^{-1}x^\top \]  

(11)

The transfer gain formula in Equation 10 ties together the variances of the data-pooling estimator becomes a diagonal matrix:

\[ \Sigma = \begin{cases} \frac{\sigma^2}{\sigma^2 + \alpha^2_S}\Sigma_S, & i \leq d_S \\ \frac{\sigma^2}{\sigma^2 + \alpha^2_T}\Sigma_T, & i > d_S \end{cases} \]

then it is straightforward to see that \( \text{Var}(\hat{\theta}_o)_{ii} \leq \text{Var}(\hat{\theta}_T)_{ii} \) and therefore \( G(x) \geq 0 \). On top of that, if we assume that our new observation \( x \) is such that \( x_i \neq 0, i \leq d_S \), then the transfer gain is strictly positive. This means that if any of the features observable in the historical data are never zero, then the generalization error of \( \hat{\theta}_o \) is strictly lower than that of \( \hat{\theta}_T \).

Theorem 5.2 could even generalize to a more complex setting where there is an arbitrary number of features that are irregularly observed. It can be done by defining multiple source datasets \((x_{S_i}, Y_{S_i})\) where each one contains complete observations of a subset of these features, and extending the loss in Equation 3 by adding an extra term \( \alpha_S R_{S_i} \) for each dataset. Again, all the features with missing observations would have to be mean-shifted and the weights would be computed as \( \alpha_{S_i} = \frac{1}{\sigma_{S_i}} \).

At this point, we know the theoretical upper bound of the error of the data-pooling estimator assuming that we have the values of \( \sigma^2_S \) and \( \sigma^2 \). In the next section, we verify the result of Theorem 5.2 empirically and also try our transfer-learning algorithm using real and simulated data.

### 6. Experimental Setup

In this section, we want to study the performance of our transfer-learning approach using real and simulated data. We do so by computing the transfer gain empirically using a held-out test set. In addition, we want to study the impact of our assumptions by checking three hypotheses:

1. Using estimations for \( \sigma^2 \) and \( \sigma^2_S \) in practice does not compromise the result of Theorem 5.2;
2. The assumption of \( \mathbb{E}[X''] = 0 \) can be achieved in practice by shifting the data using the mean estimate;
3. The result of Theorem 5.2 generalizes for non-Gaussian data.

For the first two hypotheses, we use simulated data where we know the real values for \( \sigma^2 \), \( \sigma^2_S \) and \( \mathbb{E}[X'' \) ], so we can assess how much the estimations change when the target data is scarce. The third one is tested using a public real-life dataset where we know that the data does not follow a standard normal distribution.

#### 6.1. Empirical transfer gain

Since the transfer gain depends on multiple sources of randomness, we have to estimate it empirically using multiple samples of source and target datasets. It is computed as the difference of the squared residuals of the prediction given
Algorithm 2 Empirical Transfer Gain

**Input:** number of iterations $N$, test dataset $D_{\text{test}}$

for $i = 1$ to $N$

- Randomly sample $D_S$ and $D_T$.
- Compute $\hat{\theta}_\alpha$ and $\hat{\theta}_T$.
- Compute the empirical transfer gain with Equation 13.

end for

Return the average over all $G_i$.

by the basic estimator and the prediction given by the data-pooling estimator using a held-out test dataset $D_{\text{test}}$ where all features are present. Each iteration $i$ corresponds to a different sample of training data that is used to compute $\hat{\theta}_\alpha$ and $\hat{\theta}_T$, which are then used to compute the residual difference as described in Equation 13. In the end, the empirical transfer gain is the result of the average over all the iterations. The complete procedure is detailed in Algorithm 2.

$$G_i = \frac{1}{n_{\text{test}}} \sum_{(x,y) \in D_{\text{test}}} [(y - x\hat{\theta}_T)^2 - (y - x\hat{\theta}_\alpha)^2]$$  \hspace{1cm} (13)

The way that $\hat{\theta}_\alpha$ is computed differs per experiment and is explained next.

6.2. Experiment 1

In this experiment, we want to observe how the transfer gain changes for different sizes of the target dataset $n_T$. On top of that, we want to test how accurately we can calculate $\hat{\theta}_\alpha$ if we estimate $\alpha$ using the training data samples versus using the real value of $\alpha$. For that, we simulate our data using the linear relationship $Y = 2 + 2X_1 - 2X_2 + w$, where $w, X_1, X_2 \sim \mathcal{N}(0, 1)$, so the data fits our assumptions and all the parameters necessary to compute $\alpha$ and to accurately approximate the gain are known. In each iteration, we sample $n_S = 100$ source data points where $X_2$ is omitted. We vary the size of the target dataset $n_T$ from 5 to 30 samples to assess how the transfer gain changes when there is limited target data. We repeat the procedure in Algorithm 2 for each value of $n_T$. Finally, we use 1000 held-out samples for the test set and $N = 200$ iterations.

6.3. Experiment 2

The goal of this experiment is to study the effect of shifting the target data by the sample mean when the assumption that it is zero-centered is not met. To achieve that, we compare the transfer gain of $\hat{\theta}_\alpha$ computed using the target data shifted by the real mean $E[X'']$ versus $\hat{\theta}_\alpha$ computed using the target data shifted by the sample mean $\bar{x}_T$ as described in Algorithm 1. Since we want to study this effect in isolation, we control for any other possible interfering factors by simulating the data as described in Experiment 1, except that the distribution of $X_2$ is changed to $\mathcal{N}(1, 1)$. Again we follow the procedure described by Algorithm 2 to compute the transfer gain, only that at each iteration we also have to shift the test inputs by the mean computed from the target data, so Equation 13 becomes:

$$G_i = \frac{1}{n_{\text{test}}} \sum_{(x,y) \in D_{\text{test}}} [(y - x\hat{\theta}_T)^2 - (y - (x - \bar{x}_T)\hat{\theta}_\alpha)^2]$$  \hspace{1cm} (14)

In addition, we also look at how the variance of the sample mean affects the transfer gain by repeating the simulation with different target sample sizes $n_T$. Again, we use 1000 samples for the test set and $N = 200$ iterations.

6.4. Experiment 3

In this experiment, we pick the USA Airfare dataset (U.S. Department of Transportation, 2021) to try our transfer-learning approach with publicly available real-life data. This dataset summarizes quarterly information about airfares every year from 1996 until 2021. The data is aggregated per traject, defined as pairs of origin and destination cities. It includes information such as the travel distance (nsmiles), the number of passengers, the average fare across all carriers (fare), the percentage of market share of the carrier with the largest market share (large_ms), etc. The task is to predict the fare given nsmiles and large_ms while nsmiles is always observed since the trajects do not change, but there are limited observations of large_ms. Figure 1 shows that large_ms does not follow a normal distribution neither is zero-centered (its average is around 0.56), so it violates the assumption that $X'' \sim \mathcal{N}(0, 1)$. Tables 1 and 2 show respectively general statistics and the correlations between the three variables.

We want to see whether our approach yields a positive transfer gain in the aforementioned scenario, so again we approximate it empirically using multiple samples of source and target datasets and a fixed test set. We follow the same procedure described in Experiment 2: we use the sample mean of the observations of large_ms to shift them before computing $\hat{\theta}_\alpha$ and also to shift the test observations like in

Equation 14. Again, we are interested in the case where the size of target data \( n_T \) is small and in its effect on the data-pooling estimator, so we vary it between 5 and 30 samples. The size of the source dataset is fixed as \( n_S = 100 \), considerably larger than \( n_T \). The empirical transfer gain is computed on a separate test set of 1000 points. For each value of \( n_T \), we repeat the experiment \( N = 50 \) times drawing new independent samples for the source, target, and test datasets.

7. Results

Here we analyze the results obtained from the experiments described in the previous section.

7.1. Experiment 1

Figure 2 compares the empirical transfer gain when it is computed using the true values of \( \sigma^2_S \) and \( \sigma^2 \) (the “real \( \alpha \)” line) and using their they are estimated from the data (the “estim. \( \alpha \)” line). We do so for different target dataset sizes shown in the x-axis. The result shows that the “real \( \alpha \)” curve does not go below zero, in accordance to Theorem 5.2, which means that the error of the data-pooling estimator computed on the test set is lower than that of the basic estimator. The transfer gain starts higher for small sizes of target data \( n_T \) and decreases fast as \( n_T \) increases, to the point that the transfer gain gets closer to zero. We see that the gain is highest when \( n_T \) is small, so the variance of \( \hat{\theta}_T \) is larger and the use of the source dataset helps to reduce it for \( \hat{\theta}_\alpha \). Finally, we see that the “estimated \( \alpha \)” curve overlaps almost perfectly with the real values, confirming our first hypothesis.

7.2. Experiment 2

Figure 3 shows the result of the simulation of experiment 2 where the new feature is not zero-centered, so the data-pooling estimator has to be computed by shifting the observations of that feature by its estimated mean following Algorithm 1. For the comparison, we also plot the transfer gain for \( \hat{\theta}_\alpha \) computed using the real mean. Again, we have the transfer gain in the y-axis and the target dataset size on the x-axis. We observe a difference between the gain curves of the true and the estimated mean, and the difference diminishes as \( n_T \) increases. It represents the variance of the sample mean \( \bar{x}_T \) that adds up to that of \( \hat{\theta}_\alpha \) and makes the gain smaller. The variance of \( \bar{x}_T \) is inversely proportional to \( n_T \), so it also explains why the difference is larger for small \( n_T \) and diminishes as \( n_T \) grows. Nevertheless, the transfer gain is predominantly positive when \( n_T \) is small. This shows that using the data-pooling approach can still be beneficial even in the case that the new features are not zero-centered.
7.3. Experiment 3

We visualize the result of this experiment by plotting the empirical transfer gain by the target dataset size $n_T$ in Figure 4. The result shows that the transfer gain is mostly positive for all values of $n_T$. It means that the data-pooling algorithm outperforms the basic estimator for the majority of the sampled source and target datasets and that it can generalize to data distributions different from Gaussian. It shows a pattern consistent with the simulations: the transfer gain is mainly positive and is larger when $n_T$ is small. In these cases, the size of the target dataset is too small and the variance of the basic estimator is the highest, so combining the source dataset using our transfer-learning approach is more beneficial and gives a larger gain. This result also confirms that shifting the target data by the sample mean and approximating $\alpha$ results in an approximation of $\hat{\theta}_\alpha$ which can be used in practice.

8. Conclusion

In this paper, we look at the problem of learning a predictive model after new input features are discovered, but there are only a few observations of them, while there are plenty of observations of historical data. We present a transfer-learning approach to the linear regression version of this problem that is able to bridge the difference in the input dimensions of the source and the target datasets, being the first work to the best of the authors’ knowledge to propose such an approach. We provide an in-depth theoretical study of our approach, proving an upper bound for its generalization error and its robustness against negative transfer. We also show empirically that it performs consistently better than the baseline approach when there are few target samples to train on. Our approach is simple to implement and efficient, having the same order of computational complexity as the ordinary least-squares method. In addition, it does not have any hyperparameters to tune, making it suitable for the incremental input problem since the target data is limited.

Our results rely on the assumption that the new data is unimodal and zero-centered, or that it can be normalized to fit that requirement. This aspect can be explored further in future works. A possible extension would be to relax the assumption to multi-modal data and fit a mixture of linear regression models using the expectation maximization algorithm.

An interesting next step for incremental input learning is to add the time dimension to the data so that we can have an approach applicable to time-series prediction tasks. Another future challenge is to study this problem in the non-linear case using different types of models, such as neural networks.

Transfer-Learning Across Datasets with Different Input Dimensions

A. Proof of proposition Proposition 4.1

We want to find \( \hat{\theta}_\alpha = \arg\min \mathcal{R}_\alpha(\theta) \), or \( \hat{\theta}_\alpha \) such that \( \nabla \mathcal{R}_\alpha(\hat{\theta}_\alpha) = 0 \).

By applying simple calculus rules we have \( \nabla \mathcal{R}_T(\theta) = -2x_T^\top(Y_T - x_T\theta) \) and \( \nabla \mathcal{R}_S(\theta) = -2I_Sx_S^\top(Y_S - x_S\theta) \), so we can write:

\[
\nabla \mathcal{R}_\alpha(\theta) = -2\alpha_SII_Sx_S^\top(Y_S - x_S\theta) - 2\alpha_Tx_T^\top(Y_T - x_T\theta)
\]

By equalling it to zero and solving for \( \theta \) we obtain:

\[
\hat{\theta}_\alpha = (\alpha_SII_Sx_S^\top + \alpha_Tx_T^\top x_T)^{-1}(\alpha_SII_SY_S + \alpha_Tx_T^\top Y_T)
\]

Let \( H_{\mathcal{R}_\alpha} = 2(\alpha_SII_Sx_S^\top + \alpha_Tx_T^\top x_T) \) be the Hessian matrix of \( \mathcal{R}_\alpha \). We assume that \( x_T \) is obtained from observations of \( d_T \) independent features, then the columns of \( x_T \) must be linearly independent and thus, for any vector \( v \in \mathbb{R}^{d_T} \) such that \( v \neq 0 \), \( x_Tv \neq 0 \). This means that \( x_T^\top x_Tv > 0 \) and so \( x_T^\top x_T \) is positive definite. The same holds for \( x_S^\top x_S \). Finally, \( \alpha_S \) and \( \alpha_T \) are both positive, so \( H_{\mathcal{R}_\alpha} \) is positive definite and therefore \( \mathcal{R}_\alpha \) is strictly convex and \( \hat{\theta}_\alpha \) is its global minimum. It also follows that the matrix \( M = \alpha_SII_Sx_S^\top + \alpha_Tx_T^\top x_T \) is positive definite since \( M = \frac{1}{2}H_{\mathcal{R}_\alpha} \), so the inverse \( M^{-1} \) required to compute \( \hat{\theta}_\alpha \) exists. \( \square \)

B. Proof of proposition Proposition 4.2

Let \( M = \alpha_SII_Sx_S^\top + \alpha_Tx_T^\top x_T \) and knowing that \( \theta' = \Pi^\top \theta \):

\[
\mathbb{E}[\hat{\theta}_\alpha] = \mathbb{E}[M^{-1}(\alpha_SII_SY_S + \alpha_Tx_T^\top Y_T)]
\]

\[
= \mathbb{E}[M^{-1}(\alpha_SII_SY_S) + M^{-1}(\alpha_Tx_T^\top Y_T)]
\]

\[
= M^{-1}(\alpha_SII_S\mathbb{E}[Y_S]) + M^{-1}(\alpha_Tx_T^\top \mathbb{E}[Y_T])
\]

\[
= M^{-1}(\alpha_SII_Sx_S\theta') + M^{-1}(\alpha_Tx_T^\top x_T\theta)
\]

\[
= M^{-1}(\alpha_SII_Sx_S\theta') + M^{-1}(\alpha_Tx_T^\top x_T\theta)
\]

\[
= M^{-1}(\alpha_SII_Sx_S\theta') + M^{-1}(\alpha_Tx_T^\top x_T\theta)
\]

\[
= \theta
\]

\[
\text{Var}(\hat{\theta}_\alpha) = \text{Var}(M^{-1}(\alpha_SII_SY_S + \alpha_Tx_T^\top Y_T))
\]

\[
= \text{Var}(\alpha_SM^{-1}II_Sx_S^\top Y_S) + \text{Var}(\alpha_TM^{-1}x_T^\top Y_T)
\]

\[
= \text{Var}(\alpha_SM^{-1}x_S^\top Y_S) + \text{Var}(\alpha_TM^{-1}x_T^\top Y_T)
\]

\[
= \alpha_S^2M^{-1}x_S^\top \text{Var}(Y_S)x_S^\top M^{-1} + \alpha_T^2M^{-1}x_T^\top \text{Var}(Y_T)x_T^\top M^{-1}
\]

\[
= \alpha_S^2(\sigma^2 + ||\theta''||^2)M^{-1}x_S^\top x_S^\top M^{-1} + \alpha_T^2\sigma^2M^{-1}x_T^\top x_T^\top M^{-1}
\]

\[
= M^{-1}(\alpha_S^2(\sigma^2 + ||\theta''||^2)x_S^\top x_S^\top + \alpha_T^2\sigma^2x_T^\top x_T^\top)M^{-1}
\]
C. Proof of proposition Proposition 5.1

\[ G(x) = \mathbb{E}[(Y - x\hat{\theta}_T)^2] - \mathbb{E}[(Y - x\hat{\theta}_\alpha)^2] \]
\[ = \text{Var}(Y - x\hat{\theta}_T) + \mathbb{E}[Y - x\hat{\theta}_T]^2 \]
\[ - (\text{Var}(Y - x\hat{\theta}_\alpha) + \mathbb{E}[Y - x\hat{\theta}_\alpha]^2) \]
\[ = \text{Var}(Y - x\hat{\theta}_T) + (\mathbb{E}[Y] - x\mathbb{E}[\hat{\theta}_T])^2 \]
\[ - (\text{Var}(Y - x\hat{\theta}_\alpha) + (\mathbb{E}[Y] - x\mathbb{E}[\hat{\theta}_\alpha])^2) \]
\[ = \text{Var}(Y - x\hat{\theta}_T) + (x\theta - x\hat{\theta}_T)^2 \]
\[ - (\text{Var}(Y - x\hat{\theta}_\alpha) + (x\theta - x\hat{\theta}_\alpha)^2) \]
\[ = \text{Var}(Y - x\hat{\theta}_T) - \text{Var}(Y - x\hat{\theta}_\alpha) \]
\[ = \text{Var}(Y) + \text{Var}(-x\hat{\theta}_T) - (\text{Var}(Y) + \text{Var}(-x\hat{\theta}_\alpha)) \]
\[ = \text{Var}(Y) - \text{Var}(Y) + \text{Var}(-x\hat{\theta}_T) - \text{Var}(-x\hat{\theta}_\alpha) \]
\[ = \text{Var}(-x\hat{\theta}_T) - \text{Var}(-x\hat{\theta}_\alpha) \]
\[ = x(\text{Var}(\hat{\theta}_T) - \text{Var}(\hat{\theta}_\alpha))x^T \]

D. Proof of Theorem Theorem 5.2

Let \( H = \text{Var}(\hat{\theta}_T) - \text{Var}(\hat{\theta}_\alpha) \) describe the difference between variances of \( \hat{\theta}_T \) and \( \hat{\theta}_\alpha \) such that \( G(x) = xHx^T \). We want to show that \( G(x) \geq 0 \) for any \( x \in \mathbb{R}^d \), so it suffice to prove that \( H \) is positive semi-definite. By selecting \( \alpha_S = \frac{1}{\sigma_S^2} \) and \( \alpha_T = \frac{1}{\sigma_T^2} \) we obtain \( M = \frac{1}{\sigma_S^2} I_2 \Sigma S_\perp + \frac{1}{\sigma_T^2} \Sigma_T \) and:

\[ H = \sigma^2 \Sigma^T - M^{-1}(\sigma_S^2 \alpha_S^2 I \Sigma S_\perp + \sigma_T^2 \alpha_T^2 \Sigma_T)M^{-1} \]
\[ = \sigma^2 \Sigma^T - M^{-1} \left( \frac{1}{\sigma_S^2} I \Sigma S_\perp + \frac{1}{\sigma_T^2} \Sigma_T \right) M^{-1} \]
\[ = \sigma^2 \Sigma^T - M^{-1} \Sigma S_\perp \Sigma_T M^{-1} \]
\[ = \sigma^2 \Sigma^T - M^{-1} \left( \frac{1}{\sigma_S^2} I \Sigma S_\perp + \frac{1}{\sigma_T^2} \Sigma_T \right)^{-1} \]

Let \( A = \frac{1}{\sigma_T^2} \Sigma_T, C = \frac{1}{\sigma_T^2} \Sigma_S, U = \mathbb{I} \) and \( V = \mathbb{I}^T \), \( M \) can be seen as an updated version of \( A \), so we can derive its inverse using the Woodbury identity (section 3 of (Hager, 1989)) which states that given \( A, C \) and \( A + UCV \) invertible matrices then \( M^{-1} = (A + UCV)^{-1} = A^{-1} - A^{-1}U(C^{-1} + VA^{-1}U)^{-1}VA^{-1} \):

\[ H = A^{-1} - (A + UCV)^{-1} \]
\[ = A^{-1} - (A^{-1} - A^{-1}U(C^{-1} + VA^{-1}U)^{-1}VA^{-1}) \]
\[ = A^{-1}U(C^{-1} + VA^{-1}U)^{-1}VA^{-1} \]
\[ = A^{-1}(C^{-1} + \mathbb{I}^T A^{-1} \mathbb{I})^{-1} \mathbb{I}^T A^{-1} \]

We know that \( A, A^{-1}, C, C^{-1} \) are positive definite. We also know that \( \mathbb{I} \) has full column rank and therefore \( \mathbb{I}^T A^{-1} \mathbb{I} \) is positive definite and so is \( C^{-1} + \mathbb{I}^T A^{-1} \mathbb{I} \) and its inverse. Finally, \( \mathbb{I}(C^{-1} + \mathbb{I}^T A^{-1} \mathbb{I})^{-1} \mathbb{I}^T \) is positive semi-definite and thus, since \( A^{-1} \) is symmetric, \( H \) is positive semi-definite. □
