Long-Time Convergence and Propagation of Chaos for Nonlinear MCMC

James Vuckovic (james@jamesvuckovic.com)
February 10, 2022

Abstract

In this paper, we study the long-time convergence and uniform strong propagation of chaos for a class of nonlinear Markov chains introduced in Andrieu et al. (2011) for Markov chain Monte Carlo (MCMC). Our technique is quite simple, making use of recent contraction estimates for linear Markov kernels (Hairer and Mattingly, 2011) and basic techniques from Markov theory and analysis. Moreover, the same proof strategy applies to both the long-time convergence and propagation of chaos. We also show, via some experiments, that these nonlinear MCMC techniques are viable for use in real-world high-dimensional inference such as Bayesian neural networks.

1 Introduction

In this work, we study the long-time convergence of a class of nonlinear Markov chains and the large-particle convergence of the associated interacting particle systems. The nonlinear Markov chains we will study come from applications in Markov chain Monte Carlo (MCMC), and we will apply our results to study convergence of the associated MCMC algorithms. We will also demonstrate that these MCMC algorithms work in practice.
1.1 Background

Consider the problem of evaluating expectations w.r.t. a distribution \( \pi(dx) = \exp(-V)/Zdx \) on \( \mathbb{R}^d \) for some function \( V: \mathbb{R}^d \rightarrow \mathbb{R} \) and where \( Z = \int \exp(-V(x))dx < \infty \). This problem arises in many disciplines, and is challenging because evaluating the constant \( Z \), and therefore \( \pi \) itself, is typically intractable. Hence one traditionally estimates expectations w.r.t. \( \pi \) using Monte Carlo estimates of the form

\[
E_\pi[f] \approx \frac{1}{N} \sum_{i=1}^{N} f(X^i)
\]

where \( X^i \) are independent samples from \( \pi \).

There exist various approaches to sampling from \( \pi \), but Markov chain Monte Carlo (MCMC) is perhaps the most widely used. The idea of MCMC is to use a Markov transition kernel \( P \) simulate a Markov chain \( X_{n+1} \sim P(X_n, \cdot) \) that converges rapidly to its stationary measure, designed to be \( \pi \). Therefore we can estimate

\[
E_\pi[f] \approx \frac{1}{N} \sum_{i=1}^{N} f(X^i_{\infty}) \approx \frac{1}{N} \sum_{i=1}^{N} f(X^i_{n_0})
\]

where \( n_0 \) is some large number of simulation steps and \( \{X^i_n\}_{n=0}^{\infty} \) are independent chains governed by \( P \). There is a vast literature studying various choices of \( P \); some well-known choices transition kernels are the Metropolis-Hastings algorithm (Metropolis et al., 1953; Hastings, 1970; Roberts and Tweedie, 1996a), the Gibbs sampler (Geman and Geman, 1984), the Langevin algorithm (Ermak, 1975; Roberts and Tweedie, 1996b; Durmus and Moulines, 2019), Metropolis-Adjusted Langevin (Roberts and Rosenthal, 1998), and Hamiltonian Monte Carlo (Duane et al., 1987; Betancourt, 2017; Neal, 1992, 2012; Girolami and Calderhead, 2011).

The Markov transition kernels described above simple and powerful, but can suffer from some issues. One problem is the need to properly tune the hyperparameters of an algorithm to suit the target measure — sometimes a laborious and unreliable process. Adaptive MCMC algorithms can be used to combat this issue; popular approaches include the No U-Turn Sampler (Hoffman et al., 2014), see also Andrieu and Moulines (2006); Andrieu and Thoms (2008). Another issue arises when \( \pi \) is multimodal — in this case, the Markov chain \( X_n \) can struggle to explore all modes of \( \pi \), resulting in poor sample quality. To combat this, one can use strategies such as tempering (Sambridge, 2013; Swendsen and Wang, 1986; Chandra et al., 2019), or using auxiliary Markov chains to explore some simplified version of \( \pi \) (Higdon, 1998; Habib and Barber, 2018).

Yet another class of powerful MCMC algorithms arises from allowing the transition kernel \( P \) to depend on the law (i.e. distribution) of the Markov chain as in \( X_{n+1} \sim P_{\text{Law}(X_n)}(X_n, \cdot) \). This approach gives rise to so-called nonlinear MCMC since \( \{X_n\} \) is no longer a true Markov chain. Nonlinear Markov theory is a rich area of research (McKean Jr, 1966; Méléard, 1996; Carrillo et al., 2003; Guillin and Monmarché, 2020; Sznitman, 1991; Butkovsky, 2014), and in discrete-time this has strong connections to nonlinear filtering problems (Del Moral, 1997; Del Moral and Miclo, 2001), sequential Monte Carlo (Doucet et al., 2001; Del Moral et al., 2006), and nonlinear Feynman-Kac models (Del Moral, 2004). One can replace \( \text{Law}(X_n) \), which is often intractible, with an empirical estimate

\[
\text{Law}(X_n) \approx \frac{1}{N} \sum_{i=1}^{N} \delta_{X^i_{n}}
\]

to obtain interacting particle MCMC (iMCMC, or iPMMCMC) methods; see for example Andrieu et al. (2010); Rainforth et al. (2016); Andrieu et al. (2011).
This work extends the nonlinear MCMC methods in Andrieu et al. (2011) which itself combines ideas in nonlinear Feynman-Kac models from Del Moral (2004) with auxiliary and adaptive MCMC methods. Another recent work in this direction is Clarté et al. (2019), in which they study nonlinear Metropolis-Hastings algorithms. Nonlinear MCMC is appealing because allowing the transition kernel \( P \) to depend on the law of a Markov chain allows one to leverage information from multiple samples of the process to improve on issues such as state space exploration.

However, nonlinear Markov theory has an added subtlety in that the particles \( \{X_n^1, \ldots, X_n^N\} \) of an interacting particle system are no longer independent since they interact. This means that, in addition to studying the large-time behaviour which is how classical in MCMC (Roberts and Rosenthal, 2004), one must study the large-particle behaviour to obtain Monte Carlo estimates since traditional Monte Carlo results do not apply. One such large-particle behaviour is the propagation of chaos, which roughly states that particles which begin independent will stay approximately independent over time; see Sznitman (1991). These two elements — long-time and propagation of chaos behaviour — are central to nonlinear Markov theory.

### 1.2 Contributions & Outline
The contributions of this paper are as follows:

- A simple framework to obtain quantitative long-time convergence estimates for a class of nonlinear Markov chains using basic tools from analysis and recent, albeit simple, results from linear Markov theory;
- A matching framework for quantitative, uniform-in-time strong propagation of chaos estimates for the same class of nonlinear Markov chains;
- Application of the above frameworks to two choices of nonlinear Markov kernels proposed in Andrieu et al. (2011) that are suitable for nonlinear MCMC and convergence analysis of the resulting MCMC algorithms; and
- Experiments and accompanying software implementation demonstrating that these nonlinear MCMC methods are viable in practice and may provide benefits over linear methods.

The remainder of this paper is organized as follows. Immediately below, we will establish the notation and definitions required by the rest of the paper. Following that, in Section 2, we will introduce the mean field and interacting particle systems that will be the subject of our analysis. Then, in Sections 3 and 4, we will study long-time mean-field convergence and propagation of chaos respectively. Then in Section 5 we will apply these results to MCMC, and demonstrate implementations of the resulting MCMC algorithms in Section 6. We conclude in Section 7; the proofs of most of our results are in the Appendix. The software implementation of our methods can be found at [https://github.com/jamesvuc/nonlinear-mcmc-paper](https://github.com/jamesvuc/nonlinear-mcmc-paper).

### 1.3 Notation and Definitions

#### 1.3.1 Probability Spaces, Measures, and Kernels
We will be working on the measurable space \((\mathbb{R}^d, \mathcal{B}^d)\) with \(\mathcal{B}\) the Borel \(\sigma\)-algebra\(^1\); let \(\mathcal{P}(\mathbb{R}^d)\) denote the space of probability measures on \(\mathcal{B}(\mathbb{R}^d)\). Let \(\mu \in \mathcal{P}(\mathbb{R}^d)\), \(f : \mathbb{R}^d \to \mathbb{R}\) be a measurable function, and, \(K : \mathbb{R}^d \times \mathcal{B}(\mathbb{R}^d) \to [0,1]\) be a Markov kernel. Throughout the sequel, we will write

\[
\mu(f) := \int f(x) \mu(dx), \quad Kf(x) := \int f(y)K(x, dy), \quad \mu K(dy) := \int \mu(dx)K(x, dy).
\]

\(^1\)This choice is merely for simplicity of exposition; most if not all our results will hold for any polish space and its Borel \(\sigma\)-algebra.
We denote and define as $\text{osc}(\|\cdot\|_U)$ with a family of norms on functions, and their dual norms on probability measures, which is $B$. Denote by $1.3.2$ Norms

Finally, we write $\mu$ for $\mu,\nu$ for $\mu,\nu$ for $\mu$. Note that we could replace the condition $\|x\| = (x^1,\ldots,x^q) \in (\mathbb{R}^q)^q$ and measurable $g : (\mathbb{R}^q)^q \to \mathbb{R}$.

$$f_1 \otimes \cdots \otimes f_q(x) := f_1(x^1) \cdots f_q(x^q), \mu_1 \otimes \cdots \otimes \mu_q(g) := \int g(x^1,\ldots,x^q) \mu_1(dx^1) \cdots \mu_q(dx^q).$$

When $f = f_1 = \cdots = f_q$ and $\mu = \mu_1 = \cdots = \mu_q$, we will write $f \otimes q$ and $\mu \otimes q$ respectively. Finally, we write $\mu \ll \nu$ to mean that $\nu$ dominates $\mu$ and we write $\frac{d\mu}{d\nu}$ for the Radon Nikodym derivative. The notation $\mu \sim \nu$ means that $\mu \ll \nu$ and $\nu \ll \mu$.

1.3.2 Norms

Denote by $B_b(\mathbb{R}^d)$ the set of bounded measurable functions $f : \mathbb{R}^d \to \mathbb{R}$. We will be working with a family of norms on functions, and their dual norms on probability measures, which is parameterized by functions of the form $U : \mathbb{R}^d \to [1,\infty]$. For such a $U$, we define

$$\|f\|_U := \sup_{x \in \mathbb{R}^d} \frac{|f(x)|}{U(x)}$$

for $f : \mathbb{R}^d \to \mathbb{R}$. The dual norm to $\|f\|_U$ corresponds to the weighted total variation distance; for $\mu,\nu \in \mathcal{P}(\mathbb{R}^d)$ we have

$$||\mu - \nu||_{tv,U} := \sup_{\|f\|_U \leq 1} |\mu(f) - \nu(f)|.$$  

Note that we could replace the condition $\|f\|_U \leq 1$ by $|f| \leq U$. For $V : \mathbb{R}^d \to [0,\infty]$, we will often work with $V_\beta(x) := 1 + \beta V(x)$ for $\beta > 0$; in this case, we will write $\|f\|_\beta := \|f\|_{V_\beta}$ and $\|\mu\|_{tv,\beta} := \|\mu\|_{tv,V_\beta}$. We will also need the definition of the maximum oscillation of $f$, which we denote and define as $\text{osc}(f) := \sup\{|f(x) - f(y)| \mid x,y \in \mathbb{R}^d\}$.

For Markov kernels $K,Q$ on $\mathbb{R}^d$, we obtain the weighted kernel distance

$$\|K - Q\|_{\text{ker},U} := \sup_x \frac{\|K(x,\cdot) - Q(x,\cdot)\|_{tv,U}}{U(x)}.$$  

It is worth noting the special case $U \equiv 1$ which corresponds to the usual total variation distance; in this case we will write

$$\|f\|_\infty := \|f\|_1, \quad ||\mu - \nu||_{tv} := ||\mu - \nu||_{tv,1}.$$  

Lastly, we will use the notation $c(K)$ to denote the contraction coefficient of a Markov kernel $K$ defined as $c(K) := \inf\{c \in [0,1] \mid \|\mu K - \nu K\|_{tv} \leq c\|\mu - \nu\|_{tv} \forall \mu,\nu \in \mathcal{P}\}$ see, e.g. Del Moral (2004) Ch 4.
2 Mean Field and Interacting Particle Systems

We now introduce the main stochastic processes that will be studied in this paper. The constructions fall into two categories: “mean field” models and “interacting particle system” (IPS) models.

2.1 Mean Field System

Let $K : \mathbb{R}^d \times \mathcal{B}(\mathbb{R}^d) \to [0, 1]$ be a Markov kernel, and let $J_\eta : \mathbb{R}^d \times \mathcal{B}(\mathbb{R}^d) \to [0, 1]$ be a family of Markov kernels parameterized by $\eta \in \mathcal{P}(\mathbb{R}^d)$. We are interested in the family of jump-interaction kernels

$$K_\eta(x, dy) = (1 - \varepsilon)K(x, dy) + \varepsilon J_\eta(x, dy), \quad \varepsilon \in [0, 1]$$

with $K$ creating the “internal dynamics”, $J_\eta$ creating the “jump dynamics” and $\varepsilon$ determining the “jump probability”. Let $Q : \mathbb{R}^d \times \mathcal{B}(\mathbb{R}^d) \to [0, 1]$ be another Markov kernel that we will refer to as the “auxiliary kernel”. Then, for given initial measures $\mu_0, \eta_0 \in \mathcal{P}(\mathbb{R}^d)$, we have the measure-valued flow for $n \geq 0$

$$\begin{cases}
\eta_{n+1} = \eta_n Q \\
\mu_{n+1} = \mu_n K_{\eta_{n+1}}.
\end{cases}$$

which describes the evolution of the law of nonlinear Markov chain with

$$\begin{cases}
Y_{n+1} \sim Q(Y_n, \bullet) \\
\eta_{n+1} := \text{Law}(Y_{n+1}) \\
X_{n+1} \sim K_{\eta_{n+1}}(X_n, \bullet)
\end{cases}$$

The dynamical intuition for this construction is: at every time step, we sample a new state for the auxiliary chain $Y_{n+1}$ from $Q(Y_n, \bullet)$. We then obtain the law of $Y_{n+1}$, which we denote $\eta_{n+1}$. Then $X_{n+1}$ will either evolve according to the “internal” dynamics $K(X_n, \bullet)$ with probability $(1 - \varepsilon)$ or it will “jump” to a new location determined by $X_n$ and $\eta_{n+1}$ according to the “jump” dynamics $J_{\eta_{n+1}}(X_n, \bullet)$.

2.2 Interacting Particle System

The primary difference between the interacting particle system and the mean field system is that the mean field system depends on the law of the auxiliary Markov chain, whereas the interacting particle system will depend on the empirical measure of the auxiliary Markov chain for a fixed number of samples.

Retaining the kernel from (1), let $N \in \mathbb{N}$ be fixed and let $Y_0^i \sim \eta_0$, $X_0^i \sim \mu_0$ for $i = 1, \ldots, N$. Then the particles evolve according to

$$\begin{cases}
Y_{n+1}^i \sim Q(Y_n, \bullet) \\
\eta_{n+1}^i := \text{Law}(Y_{n+1}^i) \\
X_{n+1}^i \sim K_{\eta_{n+1}^i}(X_n^i, \bullet)
\end{cases}$$

where $Y_n := (Y_n^1, \ldots, Y_n^N)$. The intuition for how this system evolves remains the same as the mean field case, except that the measure determining the jump dynamics is a random measure $m(Y_{n+1})$ rather than $\text{Law}(Y_n)$.

2.3 Nonlinear Markov Chain Monte Carlo

Now we will detail the connection between the above constructions and nonlinear MCMC. It should be obvious that the IPS (4) is the most natural choice for implementing MCMC since, in general, finding $\eta_n = \text{Law}(Y_n)$ is computationally intractable. However, the mean field system (3) provides the most natural framework for specifying choices of $K_\bullet$ with a given invariant measure as well as studying the long-time convergence properties thereof. Our strategy will
therefore be to work with the mean field system to derive “good” choices of $K_\star$ and then study the behaviour of the associated IPS as an approximation to the mean field system.

Let $\mu_\infty \in \mathcal{P}(\mathbb{R}^d)$ be a given target measure which has a density w.r.t. the Lebesgue measure (we will identify the densities with their measures in this case). We assume that $\mu_\infty$ is known only up to a normalizing constant. The goal is to specify $Q, K, J_\star$ such that $\mu_n \to \mu_\infty$ with the precise notion of convergence to be specified later. Suppose that $\eta_\infty \in \mathcal{P}(\mathbb{R}^d)$ is chosen such that it has good properties w.r.t. $\mu_\infty$; namely suppose that $\eta_\infty$ also has a density w.r.t. the Lebesgue measure and $\mu_\infty \sim \eta_\infty$ so that we may define

$$G(x) := \frac{\mu_\infty(x)}{\eta_\infty(x)}.$$  \hspace{1cm} (5)

Also assume that $\eta_\infty$ is known up to a normalizing constant. We will use the potential function $G$ to execute an approximate “change of measure” from $\eta_n \to \mu_n$ that will be an exact change of measure as $n \to \infty$. It is important to note that it is usually impossible to evaluate $G(x)$ since it contains two intractable normalizing constants.

Next suppose that $\eta_\infty$ is $Q$-invariant, i.e. $\eta_\infty Q = \eta_\infty$ and similarly suppose that $\mu_\infty$ is $K$-invariant, i.e. $\mu_\infty K = \mu_\infty$. These do not pose significant burdens in practice; $Q, K$ can (and will) be obtained from standard linear MCMC techniques such as Metropolis-Hastings (Hastings, 1970) or Langevin-based methods (Roberts and Tweedie, 1996a; Durmus and Moulines, 2019). To ensure that $\mu_\infty$ is a stationary measure of $K_{\eta_\infty}$, we should also have $\mu_\infty J_{\eta_\infty} = \mu_\infty$. Below we will investigate two choices of $J_\eta$ introduced in Andrieu et al. (2011).

**Boltzmann-Gibbs Interaction.** The first choice of $J_\star$ we will investigate, which has been studied extensively in Del Moral (2004) and related works and was used in Andrieu et al. (2011) for nonlinear MCMC, is given by

$$J_\eta(x, dy) = \Psi_G(\eta)(dy)$$

where $\Psi_G : \mathcal{P}(\mathbb{R}^d) \to \mathcal{P}(\mathbb{R}^d)$ is the Boltzmann-Gibbs transformation given by

$$\Psi_G(\eta)(dy) := \frac{G(y)}{\eta(G)} \eta(dy)$$  \hspace{1cm} (6)

whenever $\eta(G) \neq 0$. This is a nonlinear transformation with a number of interesting properties. When the potential function $G$ is a Radon-Nikodym derivative $G(x) = \frac{d\mu}{d\eta}(x)$ we can easily see that

$$\eta(G) = \int \frac{d\mu}{d\eta} d\eta = \int d\mu = 1, \quad \Psi_G(\eta)(dy) = \frac{G(y)}{\eta(G)} \eta(dy) = \frac{d\mu}{d\eta}(y) \eta(dy) = \mu(dy),$$

i.e. $\Psi_G$ is the “change of measure” operation determined by the potential function $G$. Note that, based on our choice of $G = \frac{\mu_\infty}{\eta_\infty}$ above, we intend to leverage this property. Moreover, this choice of jump kernel eliminates the intractible normalizing constants so that $\Psi_G(\eta)$ can, in principle, be evaluated for general $\eta$. Hence the first nonlinear jump interaction Markov kernel we will investigate is

$$K_{\eta}^{BG}(x, dy) := (1 - \varepsilon)K(x, dy) + \varepsilon \Psi_G(\eta)(dy).$$  \hspace{1cm} (7)

From the remarks above, is clear that $\mu_\infty$ is $K_{\eta_\infty}$-invariant.

**Accept-Reject Interaction.** The second choice of jump interaction we will study, also introduced in Andrieu et al. (2011), is

$$J_\eta(x, dy) = \alpha(x, y) \eta(dy) + (1 - A_\eta(x)) \delta_x(dy)$$
where
\[ \alpha(x, y) := 1 \land \frac{G(y)}{G(x)} = 1 \land \frac{\mu_\infty(y)\eta_\infty(x)}{\eta_\infty(y)\mu_\infty(x)} \quad \text{and} \quad A_\eta(x) := \int \alpha(x, y)\eta(dy). \] (8)

Given \( f \in \mathcal{B}_0(\mathbb{R}^d) \), we can also write this as
\[ J_\eta f(x) = \int [f(y) - f(x)]\alpha(x, y)\eta(dy) + f(x). \]

We can interpret this jump interaction as: starting in state \( x \), we jump to a new state distributed according to \( \eta(dy) \) with probability \( \alpha(x, y) \) (i.e. accept the proposed jump) and remain in the current state with probability \( 1 - A_\eta(x) \) (i.e. reject the proposed jump). Hence we obtain the accept-reject nonlinear jump interaction kernel
\[ K_\eta^{AR}(x, dy) := (1 - \varepsilon)K(x, dy) + \varepsilon[\alpha(x, y)\eta(dy) + (1 - A_\eta(x))\delta_x(dy)]. \] (9)

We will sometimes write \( J_\eta^{AR}(x, dy) \) in place of \( \alpha(x, y)\eta(dy) + (1 - A_\eta(x))\delta_x(dy) \). The form of \( J_\eta^{AR} \) is in fact an “adaptive Metropolis-Hastings” in which the proposal distribution evolves as the law of the auxiliary distribution. We can see that \( \mu_\infty \) is \( J_{\eta_\infty} \)-invariant as well:
\[
\mu_\infty(J_{\eta_\infty} f) = \int \int [f(y) - f(x)]\alpha(x, y)\eta_\infty(dy)\mu_\infty(dx) \\
= \int \int [f(y) - f(x)] 1 \land \frac{\mu_\infty(y)\eta_\infty(x)}{\eta_\infty(y)\mu_\infty(x)} \eta_\infty(dy)\mu_\infty(dx) + \mu_\infty(f) \\
= \int \int [f(y) - f(x)]\mu_\infty(x)\eta_\infty(y) \land \mu_\infty(y)\eta_\infty(x)dydx + \mu_\infty(f) \\
= \mu_\infty(f)
\]
since the integrals with \( f(y) \) and \( f(x) \) in the first term are equal.

**Simulation Algorithm.** Now we specify a practical use of the nonlinear Markov kernel \( K_\bullet \) for MCMC. This is where this work and Andrieu et al. (2011) diverge: we will provide an algorithm that uses a fixed number of samples \( N \) for MCMC. This is where this work and Andrieu et al. (2011) diverge: we will provide an algorithm that uses a fixed number of samples \( N \in \mathbb{N} \) to simulate the IPS (4), whereas Andrieu et al. (2011) investigates an algorithm in which the empirical measure is formed from all the past samples.

While the algorithm in Andrieu et al. (2011) yields a true estimate of the target measure in the limit as \( n \to \infty \) (for \( K_\bullet^{AR} \) at least, see Andrieu et al. (2011)), their MCMC algorithm’s storage complexity increases linearly with time. This behaviour is not well-suited to large-scale software implementations, which typically favour fixed-size “batches” of computations. Additionally, a practitioner cannot horizontally scale their algorithm to improve accuracy (e.g. by simply adding more samples) in a fixed time frame.

By contrast, Algorithm 1 below and the ensuing analysis use a fixed number of particles \( N \) throughout the lifetime of the algorithm. We will see that this produces a biased estimate of the target measure \( \mu_\infty \), but that this bias can be controlled both in the number of particles, \( N \), and the number of steps, \( n \). In exchange, our algorithm can be efficiently implemented in vectorized computing frameworks, as we will demonstrate in Section 6.

Additionally, let us note that the decision to use an auxiliary Markov chain is highly pragmatic. It is possible to develop “autonomous” nonlinear MCMC algorithms of the form \( \hat{\mu}_{n+1} = K_{\hat{\mu}_n} \) (see e.g. Del Moral (2004) Ch. 5) with strong theoretical guarantees but bad empirical performance. A primary reason for this is sample degeneracy: due to the properties of nonlinear interaction, in an autonomous nonlinear Markov kernel, quite often a single particle \( X_n^i \) will be given a large potential \( G(X_n^i) \) which results in the jump interaction being concentrated on a single point. From this point onwards, the algorithm will be unable to generate
enough diversity within its particles to correctly estimate the variance of the target measure. Due to the close relationship of nonlinear MCMC and nonlinear filtering, these issues have been studied in many settings such as Pitt and Shephard (1999); Andrieu et al. (2010) and using auxiliary dynamics is indeed a common solution.

Algorithm 1: Sampling from a nonlinear Markov chain with transition $K_n$.

Input: Initial samples $X^i_0 \sim \mu_0, Y^i_0 \sim \eta_0$, $i = 1, \ldots, N$
Input: Primary and auxiliary Markov kernels $K, Q$ resp. and jump kernel $J$.
Input: Number of iterations, $n_{final}$; jump probability $\varepsilon$.
Output: Set of samples $\{X^i_{n_{final}}, \ldots, X^i_N\}$.

1. for $n = 0, \ldots, n_{final-1}$ do
   // Sample auxiliary Markov chain
   2. for $i = 1, \ldots, N$ do
      3. $Y^i_{n+1} \sim Q(Y^i_n, \bullet)$
   // Sample primary Markov chain
   4. for $i = 1, \ldots, N$ do
      5. $Z^i \sim K(X^i_n, \bullet)$
   // Sample nonlinear Markov chain
   6. for $i = 1, \ldots, N$ do
      7. $B^i \sim \text{Bern}(\varepsilon)$ // Sample binary jump/no jump random variable
      8. if $B^i == 0$ then
         9. Set $X^i_{n+1} = Z^i$ // No jump; evolve according to $K$
      else
         10. Set $Y_n = \{Y^1_n, \ldots, Y^N_n\}$
         11. Sample $X^i_{n+1} \sim J_m(Y_n)(X^i_n, \bullet)$ // Jump; sample a new position.

2.4 Motivating Questions

Having established some reasonable Markov kernels for MCMC and a simulation algorithm to implement the sampling, we are left with the following general questions for the mean field and interacting particle systems:

MQ1 Does the mean field system converge to the target measure $\mu_n \to \mu_\infty$? If so, at what rate?

MQ2 Does the IPS converge to the mean field system as $N \to \infty$, i.e. $\mu^N_n := \text{Law}(X^1_n) \to \mu_n$? If so, at what rate? And does this convergence depend on $n$?

MQ3 Does the empirical measure of the IPS converge to the mean field measure, i.e. does $m(X^1_n, \ldots, X^N_n) \to \mu_n$?

Below, we will establish an affirmative answer to all of these questions under suitable settings, and with suitable notions of convergence, for $K^BG$ and $K^AR$. For MQ2, we will actually show a stronger result: a uniform propagation of chaos in which fixed-size sub-collections of particles will tend to become i.i.d. distributed according to $\mu_n$ as $N \to \infty$ uniformly in time. This will, in particular, imply an affirmative answer to MQ3.

3 Mean Field Convergence

In this section, we will study the question MQ1, i.e. whether $\mu_n \to \mu_\infty$ in an appropriate sense.
3.1 Assumptions

First are some standard drift and minorization criteria on the linear Markov kernels $K,Q$ to ensure ergodicity of those kernels.

**Assumption 1 (Drift and Minorization).** Let $K,Q : \mathbb{R}^d \times \mathcal{B}(\mathbb{R}^d) \to [0,1]$ be Markov kernels.

1. **K1** $K$ satisfies the drift criterion
   \[ KV(x) \leq aV(x) + b \]
   for $a \in [0,1]$, $b > 0$, and $V : \mathbb{R}^d \to [0,\infty[$ with $\lim_{\|x\| \to \infty} V(x) = \infty$.

2. **K2** $K$ satisfies the following uniform minorization condition on the level sets of $V$: there exists $\gamma \in [0,1]$ and $\nu \in \mathcal{P}(\mathbb{R}^d)$ and $R > 2b/(1-a)$ s.t.
   \[ \inf_{\{x \mid V(x) \leq R\}} K(x,A) \geq \gamma \nu(A) \quad \forall A \in \mathcal{B}(\mathbb{R}^d). \]

3. **Q1** $Q$ satisfies the drift criterion
   \[ QU(x) \leq \xi U(x) + c \]
   for $\xi \in [0,1]$, $c > 0$, and $U : \mathbb{R}^d \to [1,\infty[$ with $\lim_{\|x\| \to \infty} U(x) = \infty$.

4. **Q2** $Q$ satisfies the following uniform minorization condition on the level sets of $U$: there exists $\zeta \in [0,1]$ and $\nu' \in \mathcal{P}(\mathbb{R}^d)$ and $R' > 2c/(1-\xi)$ s.t.
   \[ \inf_{\{x \mid U(x) \leq R'\}} Q(x,A) \geq \zeta \nu'(A) \quad \forall A \in \mathcal{B}(\mathbb{R}^d). \]

The requirements in Assumption 1 are from Hairer and Mattingly (2011) and are by now fairly standard in the Markov chain literature. They will in particular imply the following properties for $K$ and $Q$ respectively:

**Proposition 1** (Basic Properties of $K,Q$; (Hairer and Mattingly, 2011)&(Andrieu et al., 2011)).

1. Suppose Assumptions 1-K1,K2 hold. Then there exists $\gamma \in [0,1]$ and $\beta > 0$ s.t. $\forall \mu,\nu \in \mathcal{P}(\mathbb{R}^d)$, we have
   \[ \|\mu K - \nu K\|_{tv,\beta} \leq \gamma \|\mu - \nu\|_{tv,\beta}. \]

2. Suppose that Assumptions 1-Q1,Q2 hold. Let $\eta_n = \eta_0 Q^n$ for $\eta_0 \in \mathcal{P}(\mathbb{R}^d)$, and $r \in [0,1]$. If $\eta_0(U^r) < \infty$, then for $r \in [0,1]$ there are constants $M(r) > 0$, $\delta \in [0,1]$ s.t.
   \[ \|\eta_n - \eta_\infty\|_{tv,U^r} \leq M(r)\delta^n. \]

**Proof.**

1. This is directly from Hairer and Mattingly (2011).

2. This uses Lemma 5 which shows Assumption 1 Q1,Q2 implies the assumptions in Lemma C.1 from Andrieu et al. (2011). Then we combine this with Lemma 6. Both lemmas can be found in Appendix A.

Throughout the remainder of this paper, $\beta$ and $\gamma$ will be fixed and we will adopt the notation
\[ V_\beta(x) := 1 + \beta V(x). \]

Additionally, references to $M(r)$ and $\delta$ are meant in the sense of the above proposition. Next, we introduce some criteria that ensure that the kernels $K,Q$ are “compatible” in-terms of their drift critera from Assumption 1.
Assumption 2 (Compatibility). C1 There is \( r^* \in ]0,1[ \) s.t.  
\( V_\beta(x) \leq U(x)^{r^*} \ \forall x \in \mathbb{R}^d \) with \( V_\beta \) be as above.

C2 \( G \) satisfies the lower bound compatibility criterion with \( U \): for every \( R > 0 \)  
\[ \theta(R) := \inf \{ G(x) \mid x \in \mathbb{R}^d, U(x) \leq R \} > 0. \]

Assumption 2-C1 is also present in Andrieu et al. (2011), and ensures that \( V \) and \( U \) are sufficiently “compatible”. Assumption 2-C2 is a novel assumption that we will use to obtain an \( a \ priori \) lower bound on \( \eta_n(G) \). Finally, some straightforward boundedness assumptions on \( G \).

Assumption 3 (Assumptions on \( G \)).

G1 \( G \) is bounded, i.e. \( \|G\|_\infty < \infty \).

G2 \( G \) is bounded in the weighted supremum norm for \( V_\beta \); i.e. \( \|G\|_\beta < \infty \).

### 3.2 Main Long-Time Convergence Result

We can now state the first main theorem of the paper. See Appendix A for a proof.

**Theorem 1.** Suppose that Assumption 1 and Assumption 2-C1 hold. Suppose also that \( J_\eta \) satisfies  
\[ \|J_\eta - J_{\eta'}\|_{\text{ker},\beta} \leq C_J \|\eta - \eta'\|_{\text{tv},\beta} \]  
and that  
\[ K_\eta V(x) \leq \overline{a} V(x) + \overline{b} \]  
for \( \overline{a} \in [0,1], \ \overline{b} > 0 \) and all \( \eta \in \mathcal{P}_{m_G,M_U} \) for suitably chosen constants \( m_G,M_U \). Suppose \( \delta \) is from (10) and set

**Case 1:** \( \rho := (1 - \varepsilon)\gamma \) if \( J_\eta(x,dy) \) doesn’t depend on \( x \); or

**Case 2:** \( \rho := (1 - \varepsilon)\gamma + \varepsilon\|J_{\eta_\infty} V\|_V \) if \( J_\eta(x,dy) \) does depend on \( x \).

If \( \mu_0(V),\eta_0(U) < \infty \) then there exists a constant \( C > 0 \) s.t.  
\[ \|\mu_n - \mu_\infty\|_{\text{tv},\beta} \leq \rho^n\|\mu_0 - \mu_\infty\|_{\text{tv},\beta} + Cn \max(\rho,\delta)^n. \]

In particular, if \( \rho < 1 \), we have \( \lim_{n \to \infty} \mu_n = \mu_\infty \) in \( V_\beta \)-total variation.

To apply this result to MCMC, the requirement will be to verify that the various conditions laid out in the above theorem hold for specific choices of \( K_\bullet \).

### 3.3 Convergence for Boltzmann-Gibbs Interaction

A key difficulty that arises when working with \( \Psi_G(\eta) = \frac{Gdn}{\eta(G)} \) is obtaining a uniform lower bound the denominator \( \eta(G) \). This is important for deriving uniform regularity results and for generally establishing conditions under which the measures \( \{\Psi_G(\eta_\eta)\}_{n=0}^\infty \) are well-defined. An effective approach used in Del Moral (2004) and related works is to assume the uniform lower bound \( G(x) > \epsilon > 0 \ \forall x \in \mathbb{R}^d \) for some \( \epsilon > 0 \). While this assumption is self-contained in that it works for any choice of \( \eta \), it eliminates ubiquitous families of measures such as Gaussians, e.g. \( G(x) = \exp(-\|x\|^2/2) \) and \( d\eta = dx \).

We will see below how to relax \( G(x) > \varepsilon > 0 \) using the structure of our problem. In particular, we can use the Lyapunov function \( U \) for \( Q \) to control the probability that the state \( Y_n \sim \eta_n \) will venture “far away” from the center of the state space. This leads to the intuition that, if \( G \) is sufficiently “compatible” with \( U \), i.e. the function \( G \) stays away from zero in the “center” of the state space as determined by \( U \), then the expectation \( \eta_n(G) = \mathbb{E}_\eta_n[G(Y_n)] \) can be lower-bounded using the same Lyapunov function. This insight is encoded in the compatibility criterion Assumption 2-C2, and we can use it to prove the following \( a \ priori \) lower bound on \( \eta_n(G) \).
Lemma 1. Suppose that Assumption 1-Q1 and Assumption 2-C2 hold, and let $\eta_n = \eta_{n-1}Q$ with $\eta_0(U) < \infty$. Then we have the lower bound

$$\eta_n(G) \geq \theta(R^*) \left(1 - \frac{\gamma^n \eta_0(U)}{R^*} \right)$$

where $R^*$ is fixed and doesn’t depend on $n$.

This lemma essentially says that $G$ should be bounded away from zero on the level sets of $U$. This is not a strong condition — if $G$ is bounded away from zero on compact sets and $U$ is continuous, the lemma applies. As an example, if $G = \exp(-\|x\|^2/2)$ and $U(x) = e\|x\|^2 + 1$ then this result applies. The constant $R^*$ arises since $R \mapsto \theta(R)$ is nonincreasing and $R \mapsto 1 - 1/R$ is increasing so we can optimize this bound as a function of $R$ to get $R^*$ (which may not be unique, but the value the bound attains will be). Together with the next lemma, we can obtain the desired convergence from Theorem 1 for the BG interaction.

Lemma 2. Let $\eta, \eta' \in \mathcal{P}(\mathbb{R}^d)$, and suppose that Assumption 3 holds, i.e. $\|G\|_{\infty}, \|G\|_{\beta} < \infty$. Then

$$\|\Psi_G(\eta) - \Psi_G(\eta')\|_{tv, \beta} \leq \left(\left\|\frac{\|G\|_{\beta}}{\eta(G)} + \frac{\|G\|_{\infty}}{\eta(G)}\right\| + \eta(V) \wedge \eta'(V)\beta \left\|\frac{\|G\|_{\beta}}{\eta(G)}\right\| \right) \|\eta - \eta'\|_{tv, \beta}.$$ 

Clearly, we will use our knowledge that $\eta_n \in \mathcal{P}(\mathbb{R}^d)$ to make the Lipschitz constant in Lemma 2 uniform over $\mathcal{P}(\mathbb{R}^d)$.

Proposition 2. Suppose that Assumption 1, 2, and Assumption 3-G1 hold. Then the drift criterion (12) holds uniformly over all $\eta \in \mathcal{P}(\mathbb{R}^d)$.

Now we can apply Theorem 1 to obtain convergence.

Corollary 1. Suppose that Assumptions 1, 2, 3 hold. If $\eta_0(G) > 0$, $\eta_0(U), \mu_0(V) < \infty$, then Theorem 1 holds for $K^{BG}$, i.e. the flow $\mu_n$ converges to $\mu_{\infty}$ in $V_{\beta}$-total variation as long as $\rho = (1 - \varepsilon)\gamma < 1$.

Proof. Lemma 1 and Lemma 2 imply the regularity condition (11) for constants determined by those lemmas and by noting that, due to Assumption 2-C1, $\eta(V \gamma) \leq \eta(U^{\gamma^*}) \leq \eta(U)^{\gamma^*} < \infty$ by Jensen’s inequality. Additionally, Proposition 2 implies the condition (12). Hence, since we are in “Case 1” of Theorem 1, the result follows.

3.4 Convergence for Accept-Reject Interaction

In this section, we establish the corresponding result from the previous section but for $K^{AR}$

This will not require assumption 2-C2 since the interaction is well-defined for $\eta \in \mathcal{P}(\mathbb{R}^d)$ as $\alpha(x, y)$ is in fact bounded. $K^{AR}$ is the main subject of study for Andrieu et al. (2011), and in fact the regularity and uniform drift conditions were established there. Note that the statement $\eta \in \mathcal{P}(\mathbb{R}^d)$ is vacuous since $G(x) > 0 \implies \eta(G) > 0$, and the second says that $\eta(V) < \infty$.

Lemma 3 (Andrieu et al. (2011)). Let $\eta, \eta' \in \mathcal{P}(\mathbb{R}^d)$.

Then

$$\|J^AR - J^AR\|_{ker, \beta} \leq 2\|\eta - \eta'\|_{tv, \beta}.$$ 

Lemma 4. Suppose that Assumption 1, 2-C2 hold. Then the uniform drift criterion (12) holds for $\eta \in \mathcal{P}(\mathbb{R}^d)$.

Corollary 2. Suppose that Assumption 1, 2-C2 hold. If $\eta_0(U), \mu_0(V) < \infty$, then Theorem 1 holds for $K^{BG}$, i.e. the flow $\mu_n$ converges to $\mu_{\infty}$ in $V_{\beta}$-total variation as long as $\rho = (1 - \varepsilon)\gamma + \varepsilon\|J^AV\| < 1$. 

11
4 uniform propagation of chaos

In this section, we study MQ2, i.e., the behavior of the interacting particle system (4) as \( N \to \infty \). The behavior of this system is probabilistically different from that of the mean field system (3) because the particles in (4) are coupled whereas the particles in (3) are independent. The fact that we recover independence in the limit of a collection of interchangeable particles is a remarkable feature of interacting particle systems (Sznitman, 1991).

For a collection of \( N \) particles, under suitable assumptions on \( K_\bullet \), we will show that any fixed-size \( q \)-block of particles of \( \{X_n^1, \ldots, X_n^q\} \) becomes independent as \( N \to \infty \), and moreover this trend towards independence happens uniformly in time. This phenomenon is called the uniform propagation of chaos property.\(^2\)

Let us describe the dynamics of the law of the IPS (4). From (4), each \( X_n^i \) evolves according to
\[
X_n^i \sim K_m(Y_n)(X_{n-1}^i, \bullet)
\]
which indicates that, given \( Y_n, X_n^i \) is sampled independently. Letting \( X_n^{q,N} := (X_n^1, \ldots, X_n^q) \) and \( \mu_n^{q,N} := \text{Law}(X_n^{q,N}) \in \mathcal{P}((\mathbb{R}^d)^q) \), for measurable \( f : (\mathbb{R}^d)^q \to \mathbb{R} \) one has
\[
\mu_n^{q,N}(f) = E[f(X_n^{q,N})] = E[E[f(X_n^{q,N})|Y_n]] = E[\mu_n^{q,N}K_m(Y_n)(f)]
\]
where the expectation is taken over the law of \( Y_n = (Y_n^1, \ldots, Y_n^N) \), which is \( \eta_n^{\otimes N} \). We will use this decomposition to derive a uniform propagation of chaos result in the following theorem.

**Theorem 2.** Let \( N > 0 \), \( q \in \{1, \ldots, N\} \), and consider the interacting particle system \( X_n := (X_n^1, \ldots, X_n^N) \), \( Y_n := (Y_n^1, \ldots, Y_n^N) \) from (4). Let \( \mu_n^{q,N} := \text{Law}(X_n^1, \ldots, X_n^q) \), and let \( \mu_n \) be the law of the (independent) mean field system (3), or equivalently the flow (2), with \( X_0^i \sim \mu_0 \).

Suppose that \( \forall x \in (\mathbb{R}^d)^q \) and \( f \in \mathcal{B}_b((\mathbb{R}^d)^q) \) with \( \text{osc}(f) \leq 1 \)
\[
|E[J_n^\otimes q_{m(Y)} f(x)] - J_n^\otimes q f(x)| \leq c \frac{q^2}{N} \mathcal{R}(q^2/N) , \text{ where } Y = \{Y^1, \ldots, Y^N\}, Y^i \sim \eta.
\]
Suppose finally that \( \mu_n^{q,N} = \mu^\otimes q \) for any \( 1 \leq q \leq N \).

If (Case 1): \( J_n(x, \bullet) \) doesn’t depend on \( x \), or if (Case 2): \( J_n(x, \bullet) \) does depend on \( x \) but additionally that \( \epsilon(K) < 1 \), then there exists a fixed constant \( C > 0 \) s.t.
\[
\sup_{n \geq 0} \|\mu_n^{q,N} - \mu^\otimes q\|_{tv} \leq C \frac{q^2}{N} \mathcal{R}(q^2/N).
\]

4.1 Uniform Propagation of Chaos for BG and AR Interactions

The application of the above theorem to the Boltzmann-Gibbs and Accept-Reject interactions is possible due to the following result from Del Moral (2004).

**Theorem 3** (Del Moral (2004) Thm 8.7.1 pp.283). Suppose that \( G \) has bounded oscillations, let \( N \geq q \geq 1 \), and \( Y = (Y^1, \ldots, Y^N) \), \( Y^i \sim \eta \). Then for any \( f \in \mathcal{B}_b((\mathbb{R}^d)^q) \) with \( \text{osc}(f) \leq 1 \), we have
\[
|E[\Psi_{G^{\otimes q}}(m(Y)^{\otimes q})(f)] - \Psi_{G^{\otimes q}}(\eta^{\otimes q})(f)| \leq c \frac{q^2}{N} \mathcal{R}_{G,\eta}(2q^2/N)
\]
where
\[
\mathcal{R}_{G,\eta}(u) := 1 + \text{osc}_\eta(G)^2(1 + \text{osc}_\eta(G)\sqrt{u}) \exp(\text{osc}_\eta(G)^2u), \quad \text{osc}_\eta(G) := \text{osc}(G/\eta(G)).
\]

\(^2\)here, “chaos” is synonymous with “statistical independence”, coming from the statistical physics intuition that a collection of independent particles are maximally disordered, or chaotic. This means that particles which start chaotic will approximately “propagate their chaos” through time despite interactions between the particles.

\(^3\)due to the characterization \( \|\mu - \nu\|_{tv} = \sup \{|\mu(f) - \nu(f)| \mid f \in \mathcal{B}_b(\mathbb{R}^d), \text{osc}(f) \leq 1 \} \) from Del Moral (2004) this regularity condition should be interpreted as a total variation Lipschitzness analogous to (11).
In particular, by picking $G \equiv 1$, we obtain

$$|E[m(Y)^{\otimes q}(f) - \eta^{\otimes q}(f)| \leq q^2 N.$$

**Corollary 3.** Suppose that Assumption 3 G1 holds (i.e. $G$ is bounded) the compatibility criterion Assumption 2-C2 with $\eta_\mu(G) \geq m$. Then $K_{BG}^*$ satisfies the uniform propagation of chaos in Case 1 with

$$\mathcal{R}(u) = \mathcal{R}_{G;}(u) := 1 + \frac{\text{osc}(G)^2}{m^2} \left(1 + \frac{\text{osc}(G)}{m} \sqrt{u}\right) \exp \left(\frac{\text{osc}(G)^2}{m^2} u\right)$$

**Proof.** This follows from Theorem 5 and Theorem 3 above, noting 1) that $\|G\|_\infty$ implies $\text{osc}(G) < \infty$, and 2) that we can obtain a bound on $\mathcal{R}_{G,\eta_\mu}$ independent of $\eta_\mu$ by applying Lemma 1 to obtain $\eta_\mu(G) \geq m$ so

$$\text{osc}_{\eta_\mu}(G) = \text{osc}(G/\eta_\mu(G)) \leq \text{osc}(G)/m.$$

**Corollary 4.** If $\epsilon(K) < 1$, then $K_{BG}^*$ satisfies the uniform propagation of chaos in Case 2 with $\mathcal{R} \equiv 1$.

## 5 Analysis of Nonlinear MCMC

### 5.1 Convergence of the Nonlinear MCMC Algorithm

As noted in Section 2, in applications to MCMC, we will use the interacting particle system (4) when sampling from a target distribution $\mu_\infty$. This will incur approximation errors both in time — since the target is sampled only as $n \to \infty$ — and space — since we are using a particle approximation to the mean field measure and therefore do not even sample from the invariant mean field dynamics (1). Additionally, for the IPS (4) with the BG interaction, we lose stationarity of the target measure $\mu_\infty$, since even if we could sample $Y_\infty = \{Y^1_\infty, \ldots, Y^N_\infty\}$ with $Y^i_\infty \sim \eta_\infty$, it is not generally true that $\Psi_{G}(m(Y_\infty)) = \mu_\infty$.

Hence we would like to study $\|\mu_n^N - \mu_\infty\|_{tv}$ where $\mu_n^N$ evolves according to the dynamics $\mu_n^N = \mu_{n-1}^N K_{m(Y_n)}$ or equivalently, $\mu_n^N = \text{Law}(X^1_n)$ with $X^i_n$ any particle evolving according to the IPS (4). Fortunately, the tools we have developed so far allow us to do this via the decomposition

$$\|\mu_n^N - \mu_\infty\|_{tv} \leq \|\mu_n^N - \mu_n\|_{tv} + \|\mu_n - \mu_\infty\|_{tv}.$$

In particular, our uniform propagation of chaos results in Theorem 5 and accompanying corollaries will allow us to control the first term independently of $n$, which will correspond to the approximation in space, and our $V_{\beta}$-total variation convergence in Theorem 1 will allow us to control the second term, representing the approximation in time.

**Theorem 4.** Suppose that the results of Theorem 1 and Theorem 5 apply to $K_*$ from (1). Then there exists fixed constants $C_1, C_2, C_3 > 0$ s.t.

$$\|\mu_n^N - \mu_\infty\|_{tv} \leq C_1 \frac{1}{N} \mathcal{R}(1/N) + C_2 p^n + C_3 n \max(\rho, \delta)^n.$$

**Proof.** This follows straightforwardly from the above discussion, the only technicality is converting the results from Theorem 1 to the un-weighted total variation. But note that since $\{\|f\|_\infty \leq 1\} \subset \{\|f\|_\beta \leq 1\}$ we have

$$\|\mu_n - \mu_\infty\|_{tv} = \sup_{\|f\|_\infty \leq 1} |\mu_n(f) - \mu_\infty(f)| \leq \sup_{\|f\|_\beta \leq 1} |\mu_n(f) - \mu_\infty(f)| = \|\mu_n - \mu_\infty\|_{tv,\beta}$$

so we’re done.
This result shows that, to control the approximation error \( \| \mu_n^N - \mu_\infty \|_{tv} \), it does not necessarily suffice to run the MCMC algorithm for a large number of steps \( n \), since even as \( n \to \infty \) \( \| \mu_n^N - \mu_\infty \|_{tv} \to 0 \) as long as \( N < \infty \). However, this approximation cannot lead to arbitrarily bad results: Theorem 4 provides a quantitative upper bound on how much the MCMC algorithm can be biased. Note also that this result uses total variation, which is a strong metric which represents a worst-case over all bounded functions \( f \) (up to rescaling by \( \| f \|_\infty \)). It is entirely possible that for many choices of practical \( f \) the approximation will be better, and we shall see this in the following section.

### 5.2 Convergence of Empirical Measure

While the convergence in total variation result from above provides strong guarantees on the convergence of law of the IPS to the target measure, we in practice, we will use the IPS (4) to compute a Monte Carlo approximation

\[
\mu_n(f) = E_{\mu_n}[f(X)] \approx \frac{1}{N} \sum_{i=1}^{N} f(X_i^N)
\]

for a bounded \( f \). For this application, we would like to know that the (random) empirical measure \( m(X_n) \) converges weakly to the target measure \( \mu_n \) as \( N \to \infty \); this is MQ3. (in fact, we know this convergence will hold uniformly for every \( n \) since the propagation of chaos is uniform). This also turns out to be a consequence of propagation of chaos, and the argument is due to Sznitman (1991) Proposition 2.2, which we reproduce below for completeness.

**Proposition 3 (Sznitman (1991)).** Suppose that the results of Theorem 1 and Theorem 5 apply to \( K \). Let \( X_n := \{X_1^n, \ldots, X_N^n\} \) be the IPS in (4). Then for every \( n \in \mathbb{N} \), the random measure \( m(X_n) \) converges weakly to \( \mu_n \) as \( N \to \infty \).

**Proof.** Let \( f \in B_b(\mathbb{R}^d) \) and consider

\[
E[(m(X_n)(f) - \mu_n(f))^2] = E \left[ \left( \frac{1}{N} \sum_{i=1}^{N} f(X_i^n) - \mu_n(f) \right)^2 \right]
\]

\[
= \frac{1}{N^2} \sum_{i=1}^{n} E[f(X_i^n) f(X_i^n)] - 2 \frac{N}{N} \sum_{i=1}^{N} E[f(X_i^n) \mu_n(f)] + \mu_n(f)^2
\]

\[
= \frac{1}{N} E[f(X_1^n)^2] + \frac{N}{N} E[f(X_1^n) f(X_2^n)] - 2E[f(X_1^n) \mu_n(f)] + \mu_n(f)^2
\]

using interchangeability of the \( X_i^n \)'s. Since the strong propagation of chaos in Theorem 5 clearly implies weak propagation of chaos, i.e. for any bounded \( f \) \( |\mu_{q,N}^N(f) - \mu_{q}^\otimes(f)| \to 0 \), we see that the expression above \( \to 0 \) and we have weak convergence. \( \square \)

### 6 Experiments

To demonstrate these nonlinear MCMC algorithms in practice, we perform two experiments: sampling from a multi-modal two-dimensional distribution, and Bayesian neural network parameter inference. These experiments are not meant to represent a comprehensive empirical investigation of nonlinear MCMC, but rather provide empirical evidence showing that the ideas developed in this paper can work in practice.

#### Base MCMC Sampler

Let us establish some notation. In the subsequent experiments, we will use the Metropolis-Adjusted Langevin Algorithm (MALA) (Roberts and Tweedie, 1996a)
as our linear kernels $K$ and $Q$. Specifically, for a stepsize $h$ and target measure $\pi \in \mathcal{P}(\mathbb{R}^d)$ with $C^1$ density also denoted $\pi$,

$$K^{MALA}(x, dy) = \alpha_{MH}(x, y)\kappa(x, dy) + \left(1 - \int \alpha_{MH}(x, y)\kappa(x, dy)\right)\delta_x(dy)$$  \hspace{1cm} (13)

$$\kappa(x, dy) = \mathcal{N}_d(dy; x + h\nabla \log \pi, 2hI_d)$$ \hspace{1cm} (14)

$$\alpha_{MH}(x, y) = \frac{\pi(y)\kappa(y, x)}{\pi(x)\kappa(x, y)}$$ \hspace{1cm} (15)

where $\mathcal{N}_d(dy; m, \Sigma)$ is the $d$-dimensional multivariate normal distribution with mean $m \in \mathbb{R}^d$ and covariance $\Sigma \in \mathbb{R}^{d \times d}$. This choice was made because we can leverage useful gradient information while ensuring invariance of the desired target measures (Roberts and Tweedie, 1996b).

**Software Implementation.** In Algorithm 1, we gave a high-level pseudocode implementation of the nonlinear sampler. In this implementation, for the sake of notational clarity, we used for loops to sample the individual particles. However, with modern single instruction multiple data (SIMD) computing frameworks such as GPU accelerators, this is highly inefficient. Hence one can, and should, parallelize all for loops except the outer “time” loop in Algorithm 1.

We have done this using the variety of powerful tools provided by the Jax library (Bradbury et al., 2018) within Python, such as `vmap` which allows for automatic vectorization, and seamless targeting of GPU accelerators. This becomes particularly useful for automatic batch-wise and sample-wise vectorization in the case of stochastic gradient MCMC while writing functions in-terms of single inputs and outputs. We have also leveraged the library of linear MCMC algorithms provided by the `jax-bayes` library [https://github.com/jamesvuc/jax-bayes](https://github.com/jamesvuc/jax-bayes). All experiments were run on a single Titan X GPU; the code can be found at [https://github.com/jamesvuc/nonlinear-mcmc-paper](https://github.com/jamesvuc/nonlinear-mcmc-paper).

### 6.1 Two-Dimensional Multimodal Distribution

In this section, we consider the problem of sampling from two-dimensional multimodal distributions. We use some common target distributions from the literature; the ones in this Section are from Stimper et al. (2021). This will allow us to observe the qualitative differences between linear and nonlinear MCMC methods.

For this experiment, we use the same hyperparameters for linear and nonlinear methods where applicable, see Table 1 for the values. We vary the step size $h$ of the linear kernels $K, Q$ (both MALA kernels here) to expose the level of robustness of each algorithm to different values of $h$. This simulates the case where one must calibrate the hyperparameters of a new MCMC algorithm. Note that, for the nonlinear case, the auxiliary invariant measure $\eta_\infty$ is a very simple Gaussian distribution, which does not encode any significant information about $\mu_\infty$ except that the it should be roughly centered near $(0, 0)$.

Figure 1 shows results on three multimodal distributions. We notice that, in certain cases such as the “two rings” distribution, the nonlinear MCMC algorithms display significantly better exploration of the state space and hence a more accurate sampling of all modes of the distribution. Additionally, we find that nonlinear MCMC has good stability over a range of step-sizes, particularly large ones (see Appendix C for the step-size sweep over the other two distributions). This can be useful in practice since often selecting the hyperparameters of MCMC algorithms can be a subtle task. Lastly, we notice that, for the BG interaction, the samples appear to

---

This is in contrast to the unadjusted Langevin algorithm which is not $\pi$-invariant for finite step sizes (Roberts and Tweedie, 1996b).
Table 1: Table showing the configuration of the linear and nonlinear (where applicable) MCMC samplers in the 2-dimensional experiments from Section 6.1.

“collapse” at small step sizes. This is likely because certain particles will have high probability at initialization due to chance, and since the particles cannot quickly reach regions of high probability, the BG interaction will end up over-sampling those “lucky” particles. This results in an uneven approximation of the target measure.

Figure 1: Sampling from two-dimensional, multi-modal distributions. Part (a) compares $K_{MH}$, $K_{BG}$, and $K_{AR}$ on three different multimodal distributions with step size $h = 10^{-3}$. Part (b) compares the same kernels over a range of learning rate magnitudes; see Figure 3 in Appendix C for the same experiment with the other two densities. These target densities are from Stimper et al. (2021).

6.2 Bayesian Neural Networks

Now consider the more challenging task of Bayesian parameter inference for a neural network. The basic setup, which is classical and can be found in Murphy (2012), is as follows: we are given a dataset $D = \{(x_i, y_i)\}_{i=1}^D$, a probabilistic model $p(y|x, \theta)$ parameterized by a neural network with parameters $\theta \in \mathbb{R}^d$, and a prior on parameters $P(\theta)$. The goal is to sample from

$$P(\theta|D) = \frac{P(D|\theta)P(\theta)}{P(D)} = \frac{\prod_{i=1}^D P(y_i|x_i, \theta)P(\theta)}{P(D)}$$
where we have assumed that \( P(x_i|\theta) \equiv 1 \). This will allow us to compute the posterior predictive from samples \( \{\theta^1, \ldots, \theta^N\} \) via Bayes model averaging

\[
P(y|x, D) = \int P(y|x, \theta) P(\theta|D) \approx \frac{1}{N} \sum_{i=1}^{N} P(y|x, \theta^i) P(\theta^i|D).
\]

For the dataset \( D \), we use the MNIST dataset (LeCun et al., 2010) of \( 28 \times 28 \) greyscale handwritten digit image classification. While trivial for current likelihood-based machine learning, for Bayesian methods, particularly those using MCMC, even simple neural networks can be challenging for probabilistic inference. Therefore this dataset is a simple way to demonstrate that the nonlinear MCMC we propose can apply to such high-dimensional settings.

The data likelihood \( P(y|x, \theta) \) is a categorical distribution on \( \{0, \ldots, 9\} \) representing the digits to be classified. We parameterize the unnormalized probability density using the classical 300-100-10 architecture from LeCun et al. (1998) with 253,410 parameters implemented with Haiku (Hennigan et al., 2020), i.e. we use a function \( f_\theta : \mathbb{R}^{784} \rightarrow \mathbb{R}^{10} \) to obtain

\[
P(y|x, \theta) = \frac{\exp(f_\theta(x)[y])}{\sum_{y' \in \{0, \ldots, 9\}} \exp(f_\theta(x)[y'])}.
\]

We adopt a centered isotropic multivariate Gaussian prior on \( \theta \), with a variance of 5^4.

For the MCMC algorithm, we use almost the same MALA algorithm from Section 6.1 except that we scale the noise variance by a factor of \( \sigma = 0.1 \) to obtain a proposal distribution of

\[
\kappa_\sigma(x, dy) = \mathcal{N}_d(dy; x + h\nabla \log \pi, 2h\sigma I_d).
\]

This is common in the BNN literature (see, e.g. Zhang et al. (2019)) to compensate for the fact that the probability landscape \( P(\theta|D) \) can be unstable and too much exploratory noise will slow down mixing. The actual MCMC kernel is still valid because of our Metropolis-Hastings step. Additionally, since computing the full \( P(\theta|D) \) is not practical as \( |D| = 60,000 \), we use randomly sampled minibatches \( \tilde{D} \) of size 1000 which results in a “stochastic gradient MALA”, see Welling and Teh (2011).

In this experiment, we used the BG interaction for the nonlinear kernel with a jump probability of \( \varepsilon = 0.05 \) and auxiliary target measure \( \eta(\theta) \propto P(\theta|D)^{0.9} \). In Figure 2 we compare linear and nonlinear MCMC over 5 trials using the identical base sampler (as above). We also examine the entropy of the predictive distribution separated by correct and incorrect predictions; this measures the uncertainty predicted by each model. In the same figure, we also compare with the uncertainty of an optimized model with the same network and trained to approximately the same performance.

From Figure 2, we can draw a few observations. Firstly, the nonlinear MCMC method seems to have better stability over time, despite mixing slower at the beginning of sampling. This can be seen from Figure 2(a) in which the linear MCMC method begins to drift away from a region of high probability after 5k steps, whereas the nonlinear MCMC algorithm maintains its performance. This results in the performance in Figure 2(b).

Secondly, the optimized model is overconfident in its predictions overall, which is a known phenomenon in machine learning (Gal and Ghahramani, 2016). This can be seen by comparing histogram of entropies for the optimized model vs the sampled models— for correct and incorrect predictions, the optimized model’s entropy skews significantly more towards zero (i.e. entropy is calculated as \(-\sum_{j=1}^{10} \log \bar{p}(y = c_j|x, \theta) \) for the optimized version and \(-\sum_{j=1}^{10} \log \bar{p}(y = c_j|x) \) where \( \bar{p}(y|x) = \sum_{i=1}^{N} p(y|x, \theta^i) \) approximates the predictive distribution with the parameters integrated out.)
This is an issue especially for incorrect predictions, since there is a nontrivial number of incorrect predictions for which the optimized model is apparently “very certain”. By contrast, the two Bayesian models exhibit much more reasonable levels of certainty on incorrect predictions.

Figure 2: Results from parameter inference on a 300-100-10 network (LeCun et al., 1998) for MNIST. (a) The accuracy of the posterior predictive for the linear and nonlinear algorithms as the Markov chain mixes. (b) Table of final accuracy after 10k steps ± 1 standard deviation over 5 random seeds. (c) Histogram entropies of the posterior predictive over correct and incorrect predictions for an optimized (as opposed to sampled) network with approximately the same accuracy as the BNNs. (d) Same as (c) but for a BNN sampled with the linear MCMC method. (e) Same as (d) but sampled with the nonlinear MCMC method.

7 Conclusion

In this paper, we have studied two central questions — long-time convergence and propagation of chaos — for a class of auxiliary nonlinear Markov chains that arise from applications in nonlinear MCMC. We conclude by discussing the quality of our results.

For the long-time convergence, we obtain results that are $O(n^p)$ for some constant $0 < p < 1$. While this rate certainly “fast” for practical applications, it is not geometric so we cannot claim geometric ergodicity of the nonlinear Markov chain. Geometric ergodicity is generally considered the “gold standard” of convergence and we do not see any reason why, in principle, geometric ergodicity should not hold in this case since such results are common in continuous-time, see e.g. Guillin and Monmarché (2020). However, these results use highly specialized coupling arguments whereas we have relied on simpler, and perhaps less powerful, analytical techniques. For example, Clarté et al. (2019) obtains geometric rates for an autonomous (i.e. non-auxiliary) version of $K^{AR}$ using a specialized entropy argument that would likely not apply
to the BG interaction. Nevertheless this is an intriguing direction for further investigation.

For propagation of chaos, however, our results are stronger and probably represent optimal rates. In particular, we obtain the same rates for the Boltzmann-Gibbs nonlinearity, \( O\left( \frac{q}{N^2} R_G(\frac{q}{N^2}) \right) \) as in Del Moral (2004) (since we use their key lemma). This is slightly slower than the typical \( O\left( \frac{q}{N^2} \right) \) rate for propagation of chaos but this is likely intrinsic to the nonlinearity and not a deficiency of the method. Moreover, for a better-behaved interaction such as the accept-reject interaction, we obtain strong propagation of chaos with the rate \( O\left( \frac{q}{N^2} \right) \) which is consistent with the optimal rate for linear Monte Carlo estimates. Moreover, our results are uniform in time and w.r.t. a strong norm (total variation) which is not generally obtainable from traditional coupling arguments such as those in Sznitman (1991). For example, Clarté et al. (2019) obtains a propagation of chaos result for the autonomous AR nonlinear Markov chain in the 1-Wasserstein metric which is not uniform in time, although they could likely make it uniform in time by combining with their geometric ergodicity result for the mean field system using the argument from Guillin and Monmarché (2021).

A Proofs from Section 3

A.1 Results about Weighted Total Variation

Lemma 5. Suppose that a Markov kernel $P$ satisfies a drift condition

$$PV(x) \leq aV(x) + b$$

for $V : \mathbb{R}^d \to [0, \infty]$, $V(x) \to \infty$ as $\|x\| \to \infty$, and the minorization condition with $\epsilon \in ]0,1[$, $\nu \in \mathcal{P}(\mathbb{R}^d)$, and $C := \{ x \mid V(x) \leq R \}$ s.t.

$$\inf_{x \in C} P(x, A) \geq \epsilon \nu(A).$$

holds for some $R > 2K/(1 - a)$. Then there exists $\pi \in ]a, 1[\epsilon$, $\delta > 0$, $\nu \in \mathcal{P}(\mathbb{R}^d)$, $S \in \mathcal{B}(\mathbb{R}^d)$ s.t.

$$PV(x) \leq \pi V(x) + b\mathbb{1}_{\{x \in S\}}, \quad \inf_{x \in S} P(x, A) \geq \pi \nu(A).$$

Proof. This argument merely an elaboration on the remark from the end of Hairer and Mattingly (2011). Let $\pi \in ]a, 1[\epsilon$ such that $R > b/(\pi - a)$ and $S = \{ x \mid V(x) \leq R \}$. If $x \notin S$ then

$$PV(x) \leq aV(x) + b = aV(x) + \frac{b}{V(x)} V(x) \leq aV(x) + \frac{b}{R} V(x)$$

$$\leq aV(x) + \frac{\pi - a}{b} V(x) = aV(x) + (\pi - a)V(x)$$

$$= \pi V(x).$$

If $x \in S$ then $PV(x) \leq aV(x) + b \leq \pi V(x) + b$. Hence the choices are clear from fixing $R$ as above.

Lemma 6. Let $P$ be a Markov kernel with invariant measure $\pi$ and suppose there are constants $\rho \in ]0, 1[\epsilon$, $C > 0$, and $r \in ]0, 1[\epsilon$ s.t.

$$\|P^n f - \pi(f)\|_{V^r} \leq C \rho^n \|f\|_{V^r}$$

for any $f : \mathbb{R}^d \to \mathbb{R}$ with $\|f\|_{V^r} < \infty$. Then if $\mu_0(V^r) < \infty$ and $\mu_n$ is the flow of $P$ then there is a constant $C' > 0$ s.t.

$$\|\mu_n - \mu_\infty\|_{tv, V^r} \leq C' \rho^n.$$

Proof. Consider

$$\|\mu_n - \mu_\infty\|_{tv, V^r} = \sup_{\|f\|_{V^r} \leq 1} |\mu_0 P^n f - \pi(f)|$$

$$= \sup_{\|f\|_{V^r} \leq 1} |\mu_0 (P^n f - \pi(f))|$$

$$\leq \sup_{\|f\|_{V^r} \leq 1} \mu_0 (|P^n f - \pi(f)|)$$

$$\leq \sup_{\|f\|_{V^r} \leq 1} \mu_0 (|P^n f - \pi(f)|) \|P^n f - \pi(f)\|_{V^r}$$

$$\leq C \rho^n \mu_0 (V^r) \leq C' \rho^n.$$
Proof. For the first part:

\[ \| \mu P - \nu P \|_{tv,V} = \sup_{\| f \|_V \leq 1} |\mu P(f) - \nu P(f)| \leq \sup_{\| f \|_V, \| \mu(h) - \nu(h) \|_V \leq 1} \| Pf \|_V |\mu(h) - \nu(h)| \]

and

\[ \| Pf \|_V = \sup_x \frac{| Pf(x) |}{V(x)} = \sup_x \left[ \int P(x, dy) f(y) \right] = \sup_x \left[ \int P(x, dy) V(y) \frac{f(y)/V(y)}{V(x)} \right] \leq \| f \|_V \sup_x \frac{| PV(x) |}{V(x)} \leq \sup_x \frac{aV(x) + b}{V(x)} \leq a + b. \]

For the second part, let \( \| f \|_V \leq 1 \)

\[ |\mu P(f) - \mu Q(f)| \leq \mu(\| Pf - Qf \|) \leq \mu(V) \| Pf - Qf \|_V \leq \mu(V) \| P - Q \|_{ker,V}. \]

\[ \square \]

A.2 Proof of Theorem 1

Theorem 1. Suppose that Assumption 1 and Assumption 2-C1 hold. Suppose also that \( J_\eta \) satisfies

\[ \| J_\eta - J_{\eta'} \|_{ker,\beta} \leq C_J |\eta - \eta'|_{tv,\beta} \quad (11) \]

and that

\[ K_\eta V(x) \leq \bar{a}V(x) + \bar{b} \quad (12) \]

for \( \bar{a} \in ]0,1[ \), \( \bar{b} > 0 \) and all \( \eta \in \mathcal{P}_{m_G,M_U} \) for suitably chosen constants \( m_G,M_U \). Suppose \( \delta \) is from (10) and set

Case 1: \( \rho := (1 - \varepsilon)\gamma \) if \( J_\eta(x, dy) \) doesn’t depend on \( x \); or

Case 2: \( \rho := (1 - \varepsilon)\gamma + \varepsilon\| J_{\eta_0} V \|_V \) if \( J_\eta(x, dy) \) does depend on \( x \).

If \( \mu_0(V), \eta_0(U) < \infty \) then there exists a constant \( C > 0 \) s.t.

\[ \| \mu_n - \mu_\infty \|_{tv,\beta} \leq \rho^n \| \mu_0 - \mu_\infty \|_{tv,\beta} + C \max(\rho, \delta)^n. \]

In particular, if \( \rho < 1 \), we have \( \lim_{n \to \infty} \mu_n = \mu_\infty \) in \( V_\beta \)-total variation.

Proof. Case 1: For \( n = 1 \), consider

\[ \| \mu_1 - \mu_\infty \|_{tv,\beta} = \| \mu_0 K_{\eta_1} - \mu_\infty K_{\eta_\infty} \|_{tv,\beta} \]

\[ \leq (1 - \varepsilon)\| \mu_0 K - \mu_\infty K \|_{tv,\beta} + \varepsilon \| \mu_0 J_{\eta_1} - \mu_\infty J_{\eta_\infty} \|_{tv,\beta} \]

\[ = (1 - \varepsilon)\| \mu_0 K - \mu_\infty K \|_{tv,\beta} + \varepsilon \| \mu_0 J_\eta - \mu_\infty J_\eta \|_{tv,\beta} \]

\[ \leq (1 - \varepsilon)\gamma \| \mu_0 - \mu_\infty \|_{tv,\beta} + \varepsilon C_J |\eta_1 - \eta_\infty|_{tv,\beta} \]

\[ \leq \rho \| \mu_0 - \mu_\infty \|_{tv,V} + \varepsilon C_M(\rho^*)\delta \]

\[ \leq \rho \| \mu_0 - \mu_\infty \|_{tv,V} + \varepsilon C \max(\rho, \delta) \]

because \( ^6 \)

\[ \| \eta - \eta' \|_{tv,\beta} \leq \| \eta - \eta' \|_{tv,U^*} \]

\( ^6 \)this is because \( \| f \|_{U^*} \leq \| f \|_\beta \implies \| \mu - \nu \|_{tv,\beta} \leq \| \mu - \nu \|_{tv,U^*} \)
due to the Assumption 2-C1. Hence assume true for \( n - 1 \). Then for \( n \):

\[
\|\mu_n - \mu_\infty\|_{tv,\beta} \leq (1 - \varepsilon)\|\mu_{n-1}K - \mu_\infty K\|_{tv,\beta} + \varepsilon\|\mu_{n-1}J_{\eta_n} - \mu_\infty J_{\eta_\infty}\|_{tv,\beta}
\]

\[
= (1 - \varepsilon)\|\mu_{n-1}K - \mu_\infty K\|_{tv,\beta} + \varepsilon\|J_{\eta_n} - J_{\eta_\infty}\|_{tv,\beta}
\]

\[
\leq (1 - \varepsilon)\|\mu_{n-1} - \mu_\infty\|_{tv,\beta} + \varepsilon C_J \|\eta_n - \eta_\infty\|_{tv,\beta}
\]

\[
\leq \rho \rho_{n-1}\|\mu_0 - \mu_\infty\|_{tv,\beta} + C(n - 1) \max(\rho, \delta)^{n-1} + \varepsilon C_J M(r^*) \delta^n
\]

\[
\leq \rho^n\|\mu_0 - \mu_\infty\|_{tv,\beta} + C[(n - 1) \max(\rho, \delta)^{n-1} + \max(\rho, \delta)^n]
\]

\[
= \rho^n\|\mu_0 - \mu_\infty\|_{tv,\beta} + Cn \max(\rho, \delta)^n.
\]

hence Case 1 is done.

Case 2: We proceed the same way as case 1 except we need to use

\[
\|\mu_{n-1}J_{\eta_n} - \mu_\infty J_{\eta_\infty}\|_{tv,\beta} \leq \|\mu_{n-1}J_{\eta_n} - \mu_{n-1}J_{\eta_\infty}\|_{tv,\beta} + \|\mu_{n-1}J_{\eta_\infty} - \mu_\infty J_{\eta_\infty}\|_{tv,\beta}
\]

\[
\leq \|\mu_{n-1}(V_{\beta})\|J_{\eta_n} - J_{\eta_\infty}\|_{tv,\beta} + \|J_{\eta_\infty} V_{\beta}\|\mu_{n-1} - \mu_\infty\|_{tv,\beta}
\]

using Lemma 7. Note that since \( K_* \) satisfies a uniform drift criterion for \( V \), using linearity we have

\[
\mu_n(V_{\beta}) \leq \sigma^n \mu_0(V_{\beta}) + \frac{b}{1 - \sigma} \leq \mu_0(V_{\beta}) + \frac{b}{1 - \sigma} =: C_0
\]

Hence for \( n = 1 \):

\[
\|\mu_1 - \mu_\infty\|_{tv,\beta} = \|\mu_0 K_{\eta_1} - \mu_\infty K_{\eta_\infty}\|_{tv,\beta}
\]

\[
\leq (1 - \varepsilon)\|\mu_0 K - \mu_\infty K\|_{tv,\beta} + \varepsilon\|\mu_0 J_{\eta_1} - \mu_\infty J_{\eta_\infty}\|_{tv,\beta}
\]

\[
\leq (1 - \varepsilon)\|\mu_0 K - \mu_\infty K\|_{tv,\beta} + \varepsilon\|\mu_0(V_{\beta})\|J_{\eta_1} - J_{\eta_\infty}\|_{tv,\beta} + \varepsilon\|J_{\eta_\infty} V_{\beta}\|\mu_{n-1} - \mu_\infty\|_{tv,\beta}
\]

\[
\leq (1 - \varepsilon)\|\mu_0 K - \mu_\infty K\|_{tv,\beta} + \varepsilon C_0 C_J \|\eta_1 - \eta_\infty\|_{tv,\beta}
\]

\[
\leq \rho\|\mu_0 - \mu_\infty\|_{tv,\beta} + \varepsilon C_0 C_J M(r^*) \max(\rho, \delta).
\]

Hence assume true for \( n - 1 \). Then for \( n \):

\[
\|\mu_n - \mu_\infty\|_{tv,\beta} \leq (1 - \varepsilon)\|\mu_{n-1}K - \mu_\infty K\|_{tv,\beta} + \varepsilon\|\mu_{n-1}J_{\eta_n} - \mu_\infty J_{\eta_\infty}\|_{tv,\beta}
\]

\[
\leq (1 - \varepsilon)\|\mu_{n-1}K - \mu_\infty K\|_{tv,\beta} + \varepsilon\|\mu_{n-1}(V_{\beta})\|J_{\eta_n} - J_{\eta_\infty}\|_{tv,\beta} + \varepsilon\|J_{\eta_\infty} V_{\beta}\|\mu_{n-1} - \mu_\infty\|_{tv,\beta}
\]

\[
\leq (1 - \varepsilon)\|\mu_{n-1}K - \mu_\infty K\|_{tv,\beta} + \varepsilon\|\mu_{n-1}(V_{\beta})\|J_{\eta_n} - J_{\eta_\infty}\|_{tv,\beta} + \varepsilon\|J_{\eta_\infty} V_{\beta}\|\mu_{n-1} - \mu_\infty\|_{tv,\beta}
\]

\[
\leq \rho\|\mu_0 - \mu_\infty\|_{tv,\beta} + \varepsilon \rho\|\mu_{n-1}V_{\beta}\|\mu_{n-1} - \mu_\infty\|_{tv,\beta} + \varepsilon C_0 C_J M(r^*) \max(\rho, \delta)^n
\]

\[
\leq \rho^n\|\mu_0 - \mu_\infty\|_{tv,\beta} + \varepsilon \rho^n\|\mu_{n-1}V_{\beta}\|\mu_{n-1} - \mu_\infty\|_{tv,\beta} + \varepsilon C_0 C_J M(r^*) \max(\rho, \delta)^n
\]

\[
\leq \rho^n\|\mu_0 - \mu_\infty\|_{tv,\beta} + C[(n - 1) \max(\rho, \delta)^{n-1} + \max(\rho, \delta)^n]
\]

\[
= \rho^n\|\mu_0 - \mu_\infty\|_{tv,\beta} + Cn \max(\rho, \delta)^n.
\]

hence Case 2 is done.

\[\square\]

A.3 Proofs for BG and AR Interactions

A.3.1 BG Interaction

**Lemma 1.** Suppose that Assumption 1-Q1 and Assumption 2-C2 hold, and let \( \eta_n = \eta_{n-1}Q \) with \( \eta_0(U) < \infty \). Then we have the lower bound

\[
\eta_n(G) \geq \theta(R^*) \left(1 - \frac{\gamma^n \eta_0(U) + \frac{\varepsilon}{1 + \gamma}}{R^*}\right)
\]

where \( R^* \) is fixed and doesn’t depend on \( n \).
Proof.

\[ QG(x) = \mathbb{E}_{X \sim Q(x, \cdot)}[G(X)] = \mathbb{E}_{X \sim Q(x, \cdot)}[G(X) \mathbb{1}_{\{U(X) \leq R\}} + \mathbb{E}_{X \sim Q(x, \cdot)}[G(X) \mathbb{1}_{\{U(X) > R\}}] \]
\[ \geq \theta(R) \cdot \mathbb{P}_x(U(X) \leq R) + \mathbb{E}_{X \sim Q(x, \cdot)}[G(X) \mathbb{1}_{\{U(X) > R\}}] \]
\[ \geq \theta(R) \cdot \mathbb{P}_x(U(X) \leq R). \]

But by Markov’s inequality

\[ \mathbb{P}_x(U(X) > R) \leq \frac{\mathbb{E}_x[U(X)]}{R} \leq \frac{\xi U(x) + c}{R} \]

so

\[ \mathbb{P}_x(U(X) \leq R) = 1 - \mathbb{P}_x(U(X) > R) \geq 1 - \frac{\xi U(x) + c}{R} \]

and hence

\[ QG(x) \geq \theta(R) \mathbb{P}_x(U(X) \leq R) \geq \theta(R) \left( 1 - \frac{\xi U(x) + c}{R} \right). \]

Now

\[ Q^2G(x) = Q(QG(x)) \geq Q \left( \theta(R) \left( 1 - \frac{\xi U(x) + c}{R} \right) \right) \]
\[ = \theta(R) \left( 1 - \frac{\xi U(x) + c}{R} \right) \geq \theta(R) \left( 1 - \frac{\xi^2 U(x) + c(1 + \xi)}{R} \right) \]

and iterating this procedure gives

\[ Q^nG(x) \geq \theta(R) \left( 1 - \frac{\xi^n U(x) + c}{R} \right) \]

where we have used the sum of the geometric series to obtain \( c/(1 - \xi) \). Now, \( \theta(R) \) is nonincreasing w.r.t. \( R \) and \( 1 - 1/R \) is increasing w.r.t. \( R \), so optimizing to get \( R^* \) and integrating we obtain

\[ \eta_n(G) = \eta_0(Q^nG) \geq \theta(R^*) \left( 1 - \frac{\xi^n \eta_0(U) + c}{R^*} \right). \]

Lemma 2. Let \( \eta, \eta' \in \mathcal{P}(\mathbb{R}^d) \), and suppose that Assumption 3 holds, i.e. \( \|G\|_\infty, \|G\|_\beta < \infty \). Then

\[ \|\Psi_G(\eta) - \Psi_G(\eta')\|_{tv, \beta} \leq \left( \frac{\|G\|_\beta + \|G\|_\infty}{\eta(G) \vee \eta'(G)} + \eta(V) \wedge \eta'(V) \beta \|G\|_\beta \|G\|_\infty \right) \|\eta - \eta'\|_{tv, \beta}. \]

Proof. Let \( \|f\|_\beta \leq 1 \). then

\[ |\Psi_G(\eta)(f) - \Psi_G(\eta')(f)| = \left| \int \frac{G(x)f(x)}{\eta(G)} \eta(dx) - \int \frac{G(x)f(x)}{\eta'(G)} \eta'(dx) \right| \]
\[ \leq \left| \int \frac{G(x)f(x)}{\eta(G)} \eta(dx) - \int \frac{G(x)f(x)}{\eta'(G)} \eta'(dx) \right| + \left| \int \frac{G(x)f(x)}{\eta'(G)} \eta'(dx) - \int \frac{G(x)f(x)}{\eta'(G)} \eta'(dx) \right| \]

\[ = \left| \int \frac{G(x)f(x)}{\eta(G)} \eta(dx) - \int \frac{G(x)f(x)}{\eta'(G)} \eta'(dx) \right| + \left| \int \frac{G(x)f(x)}{\eta'(G)} \eta'(dx) - \int \frac{G(x)f(x)}{\eta'(G)} \eta'(dx) \right| \]

\[ \leq \int \left| \frac{G(x)f(x)}{\eta(G)} \right| \eta(dx) + \int \left| \frac{G(x)f(x)}{\eta'(G)} \right| \eta'(dx) \]

\[ \leq \int \frac{G(x)}{\eta(G)} f(x) \eta(dx) + \int \frac{G(x)}{\eta'(G)} f(x) \eta'(dx) \]

\[ \leq \int \frac{G(x)}{\eta(G)} \cdot \frac{G(x)}{\eta'(G)} f(x) \eta(dx) + \int \frac{G(x)}{\eta'(G)} \cdot \frac{G(x)}{\eta(G)} f(x) \eta'(dx) \]

\[ \leq \frac{\|G\|_\beta}{\eta(G) \vee \eta'(G)} \int f(x) \eta(dx) + \frac{\|G\|_\beta}{\eta'(G) \vee \eta(G)} \int f(x) \eta'(dx) \]

\[ \leq \frac{\|G\|_\beta + \|G\|_\infty}{\eta(G) \vee \eta'(G)} + \eta(V) \wedge \eta'(V) \beta \|G\|_\beta \|G\|_\infty \]

\[ \|\eta - \eta'\|_{tv, \beta}. \]
for the first term

\[
\left| \int \left( \frac{G(x)f(x)}{\eta(G)} - \frac{G(x)f(x)}{\eta'(G)} \right) \eta(dx) \right|
\]

\[
\leq \frac{\|G\|_\beta \|\eta - \eta\|_{tv,\beta}}{\eta(\eta') \eta'^{\prime}(\eta)} \int G(x) f(x) |\eta(dx)|
\]

\[
\leq \frac{\|G\|_\beta \|\eta - \eta\|_{tv,\beta}}{\eta(\eta') \eta'^{\prime}(\eta)} \int G(x) f(x) |\eta(dx)|
\]

\[
\leq \frac{\|G\|_\beta \|\eta - \eta\|_{tv,\beta}}{\eta(\eta') \eta'^{\prime}(\eta)} \eta(G(1 + \beta V))\|f\|_\beta
\]

\[
= \left( \frac{\|G\|_\beta}{\eta'(\eta)} + \beta \eta(V) \frac{G\|\beta\|G\|_\infty}{\eta(\eta') \eta^{\prime}(\eta')} \right) \|\eta - \eta\|_{tv,\beta}
\]

and for the second

\[
\left| \int \frac{G(x)f(x)}{\eta'(G)} \eta(dx) - \int \frac{G(x)f(x)}{\eta'(G)} \eta'(dx) \right|
\]

\[
= \frac{1}{\eta'(G)} \left| \int G(x)f(x) \eta(dx) - \int G(x)f(x) \eta'(dx) \right|
\]

\[
\leq \frac{\|fG\|_\beta}{\eta'(G)} \|\eta - \eta\|_{tv,\beta}
\]

\[
\leq \frac{\|G\|_\infty \|f\|_\beta}{\eta'(G)} \|\eta - \eta\|_{tv,\beta} = \frac{\|G\|_\infty}{\eta'(G)} \|\eta - \eta\|_{tv,\beta}
\]

since

\[
\|fG\|_\beta = \sup_x \left| \frac{f(x)G(x)}{1 + \beta V(x)} \right| \leq \|G\|_\infty \|f\|_\beta
\]

so putting these together

\[
\|\Psi_G(\eta) - \Psi_G(\eta')\|_{tv,\beta} \leq \left( \frac{\|G\|_\beta + \|G\|_\infty}{\eta'(G)} + \eta(V) \frac{G\|\beta\|G\|_\infty}{\eta(\eta') \eta^{\prime}(\eta')} \right) \|\eta - \eta\|_{tv,\beta}
\]

Using symmetry completes the proof.

\[\square\]

**Proposition 2.** Suppose that Assumption 1, 2, and Assumption 3-G1 hold. Then the drift criterion (12) holds uniformly over all \(\eta \in P_{m,M}(\mathbb{R}^d)\).

**Proof.** Let \(\eta \in P_{m,M}(\mathbb{R}^d)\) and consider

\[
K_\eta V(x) = (1 - \epsilon)KV(x) + \epsilon \Psi_G(\eta)(V)
\]

\[
\leq (1 - \epsilon)aV(x) + (1 - \epsilon)b + \epsilon \frac{\eta(V)}{\eta(G)}
\]

\[
\leq (1 - \epsilon)aV(x) + (1 - \epsilon)b + \epsilon \frac{M}{m}.
\]

\[\square\]

**A.3.2 AR Interaction**

**Lemma 4.** Suppose that Assumption 1, 2-C2, hold. Then the uniform drift criterion (12) holds for \(\eta \in P_{0,M}(\mathbb{R}^d)\).

**Proof.** Let \(\eta \in P_{0,M}(\mathbb{R}^d)\) and consider

\[
K_\eta^{AR} V(x) = (1 - \epsilon)KV(x) + \epsilon \eta(\eta(a(x, \bullet) V) + (1 - A_\eta(x))V(x)]
\]

\[
\leq (1 - \epsilon)aV(x) + (1 - \epsilon)b + \epsilon \eta(V) + \epsilon V(x)
\]

\[
\leq [(1 - \epsilon)a + \epsilon]V(x) + (1 - \epsilon)b + \epsilon M.
\]

\[\square\]
B  Proofs from Section 4

**Theorem 5.** Let $N > 0$, $q \in \{1, \ldots, N\}$, and consider the interacting particle system $X_n := (X^1_n, \ldots, X^N_n)$, $Y_n := (Y^1_n, \ldots, Y^N_n)$ from (4). Let $\mu^{\otimes N}_n := \text{Law}(X^1_n, \ldots, X^N_n)$, and let $\mu_n$ be the law of the (independent) mean field system (3), or equivalently the flow (2), with $X_0 \sim \mu_0$. Suppose that $\forall x \in \mathbb{R}^d$ and $f \in B_b(\mathbb{R}^d)$ with $\text{osc}(f) \leq 1$.

$$|E[J_{m(Y)}^q f(x)] - J_{m(x)}^q f(x)| \leq \varepsilon \frac{q^2}{N} \mathcal{R}(q^2/N), \text{ where } Y = \{Y^1, \ldots, Y^N\}, Y^i \sim \eta.$$

Suppose finally that $\mu^{\otimes N}_0 = \mu^{\otimes N}$ for any $1 \leq q \leq N$.

If (Case 1): $J_n(x, \bullet)$ doesn’t depend on $x$, or if (Case 2): $J_n(x, \bullet)$ does depend on $x$ but additionally that $\varepsilon(K) < 1$, then there exists a fixed constant $C > 0$ s.t.

$$\sup_{n \geq 0} \|\mu^{\otimes N}_n - \mu^{\otimes q}_n\|_{tv} \leq C \frac{q^2}{N} \mathcal{R}(q^2/N).$$

**Proof.** Case 1: We first claim that

$$\|\mu^{\otimes q}_{n+1} - \mu^{\otimes q}_{n+1}\|_{tv} \leq c \varepsilon \sum_{j=0}^{n-1} (1 - \varepsilon)^j \varepsilon(K^{\otimes q})^j \cdot \frac{q^2}{N} \mathcal{R}(2q^2/N).$$

Let $f \in B_b((\mathbb{R}^d)^q)$ s.t. $\text{osc}(f) \leq 1$.

Consider the following expression for general $n$:

$$|\mu^{\otimes q}_{n+1}(f) - \mu^{\otimes q}_{n+1}(f)| = |E[\mu^{\otimes q}_{n+1} K_{m(Y_1)}(f)] - \mu^{\otimes q}_{n+1} K_{m(Y_1)}(f)|$$

$$= |E[\mu^{\otimes q}_{n+1} K_{m(Y_1)}(f) - \mu^{\otimes q}_{n+1} K_{m(Y_1)}(f) + \mu^{\otimes q}_{n+1} K_{m(Y_1)}(f) - \mu^{\otimes q}_{n+1} K_{m(Y_1)}(f)]$$

$$\leq |E[\mu^{\otimes q}_{n+1} K_{m(Y_1)}(f) - \mu^{\otimes q}_{n+1} K_{m(Y_1)}(f)] + |\mu^{\otimes q}_{n+1} K_{m(Y_1)}(f) - \mu^{\otimes q}_{n+1} K_{m(Y_1)}(f)|$$

$$\leq \sup_{x} \varepsilon |E[J_{m(Y)}^q f(x)] - J_{m(Y)}^q f(x)| + (1 - \varepsilon)|\mu^{\otimes q}_{n+1} K_{m(Y)}(f) - \mu^{\otimes q}_{n+1} K_{m(Y)}(f)|$$

$$\leq c \varepsilon \frac{q^2}{N} \mathcal{R}(q^2/N) + (1 - \varepsilon)\varepsilon(K^{\otimes q})|\mu^{\otimes q}_{n+1} (f) - \mu^{\otimes q}_n (f)|.$$

where we have used the assumption on $J$.

Thus if $n = 1$ in the above expression, the base case holds since $\mu^{\otimes q}_0 = \mu^{\otimes q}_0$. Now, if the claim holds for $n$, then for $n+1$ we have

$$|\mu^{\otimes q}_{n+1}(f) - \mu^{\otimes q}_{n+1}(f)| \leq c \varepsilon \frac{q^2}{N} \mathcal{R}(q^2/N) + (1 - \varepsilon)\varepsilon(K^{\otimes q})\varepsilon \sum_{j=0}^{n-1} (1 - \varepsilon)^j \varepsilon(K^{\otimes q})^j \cdot \frac{q^2}{N} \mathcal{R}(q^2/N)$$

$$= c \varepsilon \frac{q^2}{N} \mathcal{R}(q^2/N) \left[1 + (1 - \varepsilon)\varepsilon(K^{\otimes q}) \sum_{j=0}^{n-1} (1 - \varepsilon)^j \varepsilon(K^{\otimes q})^j \right]$$

$$= c \varepsilon \frac{q^2}{N} \mathcal{R}(q^2/N) \sum_{j=0}^{n} (1 - \varepsilon)^j \varepsilon(K^{\otimes q})^j.$$

Thus the claim holds for $n+1$. Since $(1 - \varepsilon)\varepsilon(K^{\otimes q}) < 1$, we have the result.

Case 2: We first claim that

$$\|\mu^{\otimes q}_{n+1} - \mu^{\otimes q}_{n+1}\|_{tv} \leq c \varepsilon \sum_{j=0}^{n-1} (1 - \varepsilon)^j \varepsilon(K^{\otimes q})^j \cdot \frac{q^2}{N} \mathcal{R}(q^2/N)).$$

---

7 due to the characterization $\|\mu - \nu\|_{tv} = \sup \{|\mu(f) - \nu(f)| \mid f \in B_b(\mathbb{R}^d), \text{osc}(f) \leq 1\}$ from Del Moral (2004) this regularity condition should be interpreted as a total variation Lipschitzness analogous to (11).
Let $f \in B_b((\mathbb{R}^d)^q)$ with $\text{osc}(f) \leq 1$. We proceed by induction. Note that:

$$|\mu_{n+1}^{q,N}(f) - \mu_{n+1}^{\otimes q}(f)| = |E[\mu_{n}^{q,N}K_{mY_n}] - \mu_{n}^{\otimes q}K_{mY_n}(f)|$$

$$= \varepsilon|E[\mu_{n}^{q,N}J_{mY_n}(f)] - \mu_{n}^{\otimes q}J_{\eta_n}(f)| + (1 - \varepsilon)|\mu_{n}^{q,N}K(f) - \mu_{n}^{\otimes q}K(f)|$$

for the first term, we will use the decomposition

$$|E[\mu_{n}^{q,N}J_{mY_n}(f)] - \mu_{n}^{\otimes q}J_{\eta_n}(f)| \leq |E[\mu_{n}^{q,N}J_{mY_n}(f)] - \mu_{n}^{q,N}J_{\eta_n}(f)| + |\mu_{n}^{q,N}J_{\eta_n}(f) - \mu_{n}^{\otimes q}J_{\eta_n}(f)|$$

Then, using the assumption on $J$, we have

$$|E[\mu_{n}^{q,N}J_{mY_n}(f)] - \mu_{n}^{q,N}J_{\eta_n}(f)| \leq c\frac{q^2}{N}\mathcal{R}(q^2/N)$$

and also we know we can use

$$|\mu_{n}^{q,N}J_{\eta_n}f - \mu_{n}^{\otimes q}J_{\eta_n}f| \leq \text{osc}(J_{\eta_n}f)|\mu_{n}^{q,N}(h) - \mu_{n}^{\otimes q}(h)|$$

$$\leq \epsilon(J_{\eta_n})\text{osc}(f)|\mu_{n}^{q,N}(h) - \mu_{n}^{\otimes q}(h)|$$

$$\leq |\mu_{n}^{q,N}(h) - \mu_{n}^{\otimes q}(h)||$$

since $\epsilon(J_{\eta_n}) \leq 1$, with $\text{osc}(h) \leq 1$. Hence putting these together, we see

$$|\mu_{n+1}^{q,N}(f) - \mu_{n+1}^{\otimes q}(f)| \leq c\frac{q^2}{N}\mathcal{R}(q^2/2N) + \varepsilon|\mu_{n}^{q,N}(h) - \mu_{n}^{\otimes q}(h)| + (1 - \varepsilon)\epsilon(K^{\otimes q})|\mu_{n}^{q,N}(f) - \mu_{n}^{\otimes q}(f)|$$

$$\leq c\frac{q^2}{N}\mathcal{R}(q^2/2N) + (\varepsilon + (1 - \varepsilon)\epsilon(K^{\otimes q}))\|\mu_{n}^{q,N}(f) - \mu_{n}^{\otimes q}(f)\|_{tv}.$$ 

Now if $n = 0$ in the above expression, the base case holds since $\mu_0^{q,N} = \mu_0^{\otimes q}$. If it is true for $n$, then for $n + 1$ we have

$$|\mu_{n+1}^{q,N}(f) - \mu_{n+1}^{\otimes q}(f)| = |E[\mu_{n}^{q,N}K_{mY_n}] - \mu_{n}^{\otimes q}K_{\eta_n}f|$$

$$\leq c\frac{q^2}{N}\mathcal{R}(q^2/N) + (\varepsilon + (1 - \varepsilon)\epsilon(K^{\otimes q}))\|\mu_{n}^{q,N}(f) - \mu_{n}^{\otimes q}(f)\|_{tv}$$

$$\leq c\frac{q^2}{N}\mathcal{R}(q^2/N) + (\varepsilon + (1 - \varepsilon)\epsilon(K^{\otimes q}))\left[ce\sum_{j=0}^{n-1}[\varepsilon + (1 - \varepsilon)\epsilon(K^{\otimes q})]^j \cdot \frac{q^2}{N}\mathcal{R}(2q^2/N)\right]$$

$$= c\frac{q^2}{N}\mathcal{R}(q^2/N)\left[1 + \sum_{j=1}^{n}[\varepsilon + (1 - \varepsilon)\epsilon(K^{\otimes q})]^j\right]$$

$$= c\frac{q^2}{N}\mathcal{R}(q^2/N)\sum_{j=0}^{n}[\varepsilon + (1 - \varepsilon)\epsilon(K^{\otimes q})]^j.$$ 

Hence if $\epsilon(K^{\otimes q}) < 1$, i.e. $\epsilon(K) < 1$, the result holds. \hfill \Box 

B.1 Results for BG and AR Intertactions

Lemma 8. Let $\eta \in \mathcal{P}(\mathbb{R}^d)$ be s.t. $\eta(G) \neq 0$. Then

$$\Psi_G(\eta)^{\otimes q} = \Psi_{G^{\otimes q}}(\eta^{\otimes q}).$$

Proposition 4. Let $J = J^{AR}$, and $Y = \{Y^1, \ldots, Y^N\}$ where $Y^i \stackrel{iid}{\sim} \eta$. Then for any $f \in B_b((\mathbb{R}^d)^q$ with $\text{osc}(f) \leq 1$ and $x \in (\mathbb{R}^d)^q$, we have

$$|E[J_{mY}^\otimes f(x)] - J_\eta^{\otimes q}f(x)| \leq 2c\frac{q^2}{N}.$$
Proof. Starting with the first term, for each fixed $x$

\[
|E[J_{m(Y_n)}^{\otimes q} f(x)] - J_{\eta_n}^{\otimes q} f(x)| = |E\left[\int [f(y) - f(x)]\alpha^{\otimes q}(x,y)m(Y_n)^{\otimes q}(dy)\right] - \int [f(y) - f(x)]\alpha^{\otimes q}(x,y)\eta_n^{\otimes q}(dy)|
\]

\[
= |E[m(Y_n)^{\otimes q}(\varphi_f(x,\bullet))] - \eta_n^{\otimes q}(\varphi_f(x,\bullet))|
\]

where \[
\varphi_f(x, y) := \alpha^{\otimes q}(x,y)[f(y) - f(x)].
\]

Now

\[
\sup_y |\varphi_f(x, y)| = \sup_y |[f(y) - f(x)]\alpha^{\otimes q}(x,y)| \leq \sup_y |f(y) - f(x)||\alpha^{\otimes q}(x,\bullet)||_{\infty} \leq \operatorname{osc}(f) \leq 1
\]

so automatically \(\operatorname{osc}(\varphi_f(x, \bullet)) \leq 2\). Hence using Lemma 3

\[
|E[m(Y_n)^{\otimes q}(\varphi_f(x, \bullet))] - \eta_n^{\otimes q}(\varphi_f(x, \bullet))| \leq 2c \frac{q^2}{N}.
\]

\[\square\]

C Additional Experimental Results
Figure 3: Additional Results from Figure 1; the same setup applies here.
