Abstract

We study the problem of transfer-learning in the setting of stochastic linear bandit tasks. We consider that a low dimensional linear representation is shared across the tasks, and study the benefit of learning this representation in the multi-task learning setting. Following recent results to design stochastic bandit policies, we propose an efficient greedy policy based on trace norm regularization. It implicitly learns a low dimensional representation by encouraging the matrix formed by the task regression vectors to be of low rank. Unlike previous work in the literature, our policy does not need to know the rank of the underlying matrix. We derive an upper bound on the multi-task regret of our policy, which is, up to logarithmic factors, of order $\sqrt{NdT(T+d)r}$, where $T$ is the number of tasks, $r$ the rank, $d$ the number of variables and $N$ the number of rounds per task. We show the benefit of our strategy compared to the baseline $Td\sqrt{N}$ obtained by solving each task independently. We also provide a lower bound to the multi-task regret. Finally, we corroborate our theoretical findings with preliminary experiments on synthetic data.

1 Introduction

Contextual bandits (Abbasi-Yadkori et al., 2011; Li et al., 2010; Auer, 2002) are a prominent learning framework to study sequential decision problems with partial feedback. They find applications in numerous fields, ranging from recommender systems (Li et al., 2010), to finance (Shen et al., 2015) and to adaptive routing (Awerbuch and Kleinberg, 2008), among others. This methodology was originally motivated by applications in clinical trials (Woodroofe, 1979), whereby a doctor has to decide which among available treatments is best suited for a patient, through a sequence of trials. A fundamental aspect in bandit problems is to control the trade-off between exploration and exploitation, namely, the balance between the need of acquiring more information and the temptation to act optimally according to the already available knowledge. In this paper we study multi-task learning with stochastic linear contextual bandit tasks (Lu et al., 2021; Li et al., 2017; Filippi et al., 2010). In this setting, a learning agent faces different linear bandit tasks. During each interaction, the agent is presented with a set of different alternatives (usually referred to as arms) each
of which is associated with a feature vector. The agent has to select one option and subsequently observes a stochastic reward generated from an unknown linear regression of the chosen vector.

We consider the case where there exists a common low dimensional representation that is shared among the tasks. The benefit of learning such a representation has been widely investigated in both the standard supervised learning and in the reinforcement learning settings (Lounici et al., 2011; Negahban and Wainwright, 2011; Calandriello et al., 2014). In the bandit setting, obtaining the same benefit is a nontrivial task since samples are no longer independently distributed. Indeed, contexts (samples) are collected sequentially depending on past observations and on the adopted bandit policy. This entails two main challenges. On the one hand, we would like the collected contexts to span the whole feature space, as this would facilitate the estimation the unknown regression vectors. On the other hand, collecting contexts which are misaligned with respect to the regression vector results in poor performance for the bandit strategy. Preliminary and insightful results referred to a setting similar to ours have been recently investigated in (Yang et al., 2020; Hu et al., 2021). However, the approaches proposed in those papers are based on inefficient methods which also assume to have access to unknown problem parameters. In this work we present a different approach which aim to overcome their weaknesses.

Related Works. In the last two decades many efforts have been devoted to designing contextual bandit policies (Abbasi-Yadkori et al., 2011, 2012; Ariu et al., 2020; Auer, 2002; Bastani and Bayati, 2020; Chu et al., 2011; Kim and Paik, 2019; Li et al., 2017; Oh et al., 2021; Wang et al., 2018; Kuzborskij et al., 2019). When restricting to the high-dimensional setting an appealing approach is based on sparse linear models, i.e. the number $s$ of non-zero components of the regression vector is assumed to be much smaller than the input dimension $d$. Many different strategies have been investigated (Kim and Paik, 2019; Ariu et al., 2020; Bastani and Bayati, 2020). Among the proposed approaches, one of the most recent and valuable works is (Oh et al., 2021), where they design a greedy policy suitable to the generalized linear bandit setting which is based on the Lasso estimator. Interestingly, their approach does not require one to know the value $s$ and it does not perform random pulls in order to have i.i.d. data. Inspired by their contribution, we propose a greedy algorithm which does not need to know the rank index $r$. A technical challenge that we are facing is how to obtain an accurate estimator relying on non i.i.d. data, while considering a more complex estimator. We observe that their regret bound argument is not accurate as there might be a hidden dependency in the number of features (the same inaccuracy can be found in (Cella and Pontil, 2021; Kim and Paik, 2019; Calandriello et al., 2014)) and we provide a matching lower bound under the restricted eigenvalue conditions.

We also mention that (Kveton et al., 2017) studied low-rank stochastic bandits. However they consider a completely different protocol, regret and arms definitions. Thus it is not possible to draw a quantitative comparison to this work.

Multi-task and meta-learning frameworks have been studied primarily in the supervised-learning setting (Tripuraneni et al., 2021; Denevi et al., 2018; Lounici et al., 2011; Argyriou et al., 2008; Baxter, 2000). Specifically, the impact of representation learning with trace-norm regularization has been widely investigated when considering i.i.d. data (Koltchinskii et al., 2011; Negahban and Wainwright, 2011; Maurer and Pontil, 2013). More recently different authors have investigated the combination of multi-task and meta-learning with interactive learning settings (e.g. bandits and reinforcement learning) (Hu et al., 2021; Basu et al., 2021; Cella and Pontil, 2021; Kveton et al., 2021; Simchowitz et al., 2021; Calandriello et al., 2014; D’Eramo et al., 2019; Cella et al., 2020; Yang et al., 2020). Among the latter category, the most relevant works are (Yang et al., 2020; Hu et al., 2021; Cella and Pontil, 2021). In (Cella and Pontil, 2021) authors considered both the multi-task and the meta-learning frameworks but assuming the task vector parameters to be jointly sparse, which is more restrictive than the low rank assumption considered here. Differently, (Yang et al., 2020; Hu et al., 2021; Cella and Pontil, 2021). In (Cella and Pontil, 2021) authors considered both the multi-task and the meta-learning frameworks but assuming the task vector parameters to be jointly sparse, which is more restrictive than the low rank assumption considered here. Differently, (Yang et al., 2020; Hu et al., 2021; Cella and Pontil, 2021).
et al., 2021) consider a more general low-rank assumption, which include the one considered here in the case of linear models. Yet, the policies considered in those papers require knowledge of the low-rank parameter \( r \) and are not sample efficient. In this work, we develop a different and more general analysis along with a computationally efficient strategy which does not requires one to know the low-rank parameter \( r \). Our idea is similar to the last approach investigated in (Calandriello et al., 2014), but their work considers the simpler case where samples are given i.i.d.. Besides the hidden dependency imprecision mentioned before, we also observe that their proof is invalid since it relies on a erroneous concentration argument.

Contributions and Organization. The contributions of this work are threefold. First, we provide oracle inequalities for the trace norm regularized estimator under the restricted strong convexity condition with correct and explicit dependencies (Section 3). Note that this result is based on a novel martingale concentration argument. Second, we propose a regret-minimization policy that does not require random plays to get i.i.d. data or to know the rank value \( r \) (Section 4) for which we provide an upper bound on the multi-task regret (Section 4). Third, in order to evaluate how good our upper bound is, we establish a novel lower bound argument for the multi-task regret in Section 5. There we also present a lower-bound argument for the single-task sparse linear bandit problem, answering an open question about the optimality of the policy in (Oh et al., 2021). Finally, in Section 6 we present preliminary experiments on synthetic data supporting our theoretical findings.

Notation. For a real vector \( x \in \mathbb{R}^d \), we use \( \| x \| \) to denote its euclidean norm. Given a pair of symmetric matrices \( A, B \in \mathbb{R}^{d \times d} \), the expression \( A \succeq B \) means that \( A - B \) is positive semi-definite. We respectively use \( \lambda_{\text{min}}(A) \) and \( \lambda_{\text{max}}(A) \) to refer to the minimum and maximum eigenvalues of a square symmetric matrix \( A \). Similarly, we respectively use \( \sigma_{\text{min}}(A) \) and \( \sigma_{\text{max}}(A) \) for the smallest and the largest singular values associated to a generic matrix \( A \). Given a positive definite matrix \( A \succ 0 \), we indicate with \( \| x \|_A = \sqrt{x^T A x} \) the corresponding weighted Euclidean norm. For any matrix \( A \in \mathbb{R}^{d \times T} \), we let \( \| A \|_* = \sum_{i=1}^d \sigma_i(A) \) be the trace norm (sum of its singular values), \( \| A \|_F \) the Frobenius norm and \( \| A \|_{\text{op}} = \sigma_{\text{max}}(A) \) the operator norm (largest singular value). We denote with \( [A]^i \) its \( i \)-th row and with \( [A]_j \) its \( j \)-th column. Finally, we use \( \text{diag}(\lambda_1, \ldots, \lambda_d) \) for the \( d \times d \) diagonal matrix with values \( \lambda_1, \ldots, \lambda_d \) on the diagonal. Given a random event \( \Upsilon \), we denote with \( \Upsilon^c \) its complement. Finally, given a scalar \( \epsilon \in \mathbb{R} \) we denote with \( \epsilon_d \) the \( d \)-dimensional vector having value \( \epsilon \) in each component. Additional notation is introduced on the way; a table summarizing the notation used throughout the paper is reported in the appendix.

2 Problem Setting

In this section we recall the stochastic linear contextual bandit formalism and then introduce the multi-task learning framework.

2.1 Preliminaries on Linear Contextual Bandits

The contextual linear bandit problem consists of a sequence of \( N \) interactions between a learning policy \( \pi \) and the environment. At each round \( n \in [N] \), the agent is given a set of alternatives \( D_n \subseteq \mathbb{R}^d : |D_n| = K \) from which it has to select one arm \( x_n \in D_n \) among the \( K \) available ones. Then, the agent observes the corresponding reward \( Y_n \) which is assumed to be a random variable. When considering linear contextual bandits, the observed reward satisfies

\[
Y_n = x_n^T w + \eta_n, \tag{1}
\]
Finally, we assume that \( \| \eta_n \| \) is assumed to be a random variable whose statistical distribution will be specified later. By knowing the true regression vector \( \mathbf{w} \), at each round \( n \in [N] \) the optimal policy \( \pi^* \) selects \( \mathbf{x}_{n}^* = \arg \max_{\mathbf{x} \in \mathcal{D}_n} \mathbf{x}^\top \mathbf{w} \), maximizing the instantaneous expected reward. The learning objective is then to maximize the cumulative reward, or equivalently, to minimize the pseudo-regret

\[
R(N, \mathbf{w}) = \sum_{n=1}^{N} r_n = \sum_{n=1}^{N} (\mathbf{x}_{n}^* - \mathbf{x}_n)^\top \mathbf{w}.
\]

We make the following additional assumptions on the arms, the regression vector and the noise variables.

**Assumption 1** (Feature set and parameter). All arms have bounded norm, that is, for every \( \mathbf{x} \in \bigcup_{n \in [N]} \mathcal{D}_n \) it holds that \( \| \mathbf{x} \|_\infty \leq b \). At each round \( n \in [N] \), the decision set \( \mathcal{D}_n \in \mathbb{R}^d \) consists of \( K \) \( d \)-dimensional vectors. Specifically, we assume the tuples \( \mathcal{D}_1, \ldots, \mathcal{D}_N \) to be drawn i.i.d. from an fixed by unknown zero mean subGaussian joint distribution \( p \) on \( \mathbb{R}^{Kd} \). We denote by \( C_\mathbf{x} \) the subGaussian Orlicz norm of the \( K \) marginal distributions of \( p \) corresponding to the \( K \) arms, that is

\[
C_\mathbf{x} := \max_{1 \leq k \leq K} \{ \| \mathbf{x}_k \|_{\psi_2} \} < \infty.
\]

Finally, we assume that \( \| \mathbf{w} \|_1 \leq L \), for some constant \( L > 0 \).

We denote by \( C_{\psi_2} \) the subGaussian norm of this joint distribution (see e.g. Vershynin, 2018, Chap. 2). Note that from Assumption 1 it follows that each arm \( \mathbf{x}_k \) admits zero mean, square-integrable marginal distribution with \( d \times d \) covariance operator \( \Sigma_k \). Hence, vectors associated to different arms are allowed to be correlated between each other. This kind of assumption is quite standard when considering high-dimensional linear bandits (Bastani and Bayati, 2020; Hao et al., 2020; Kim and Paik, 2019; Rusmevichientong and Tsitsiklis, 2010). It ensures the regret at any interaction \( n \in [N] \) to be bounded. Indeed, thanks to Hölder’s inequality for the \( \ell_1 \) and \( \ell_\infty \) norms, we have that \( r_n \leq 2Lb \). Finally, similarly to (Oh et al., 2021), we introduce the following assumption for the previously discussed arms distribution. This mild condition will be necessary for the analysis in order to control the satisfaction of specific regularity property (the RSC condition, see Definition 1) by the empirical covariance matrix. Specifically, it will allow the designed policy to avoid interleaving its arm selection strategy with random plays.

**Assumption 2** (Arms distribution). There exists a constant \( \nu < \infty \) such that \( p(-\mathbf{x})/p(\mathbf{x}) \leq \nu \ \forall \mathbf{x} \in \mathbb{R}^{Kd} \). Additionally, let us consider a permutation \( (a_1, \ldots, a_K) \) of \( (1, \ldots, K) \). For any integer \( i \in \{2, \ldots, K-1\} \) and any fixed vector \( \mathbf{w} \in \mathbb{R}^d \), there exists a constant \( \omega_X < \infty \) such that

\[
\mathbb{E} \left[ \mathbf{x}_{a_i} \mathbf{x}_{a_i}^\top \mathbb{P} \left\{ \mathbf{x}_{a_i}^\top \mathbf{w} < \cdots < \mathbf{x}_{a_K}^\top \mathbf{w} \right\} \right] \leq \omega_X \mathbb{E} \left[ \left( \mathbf{x}_{a_1} \mathbf{x}_{a_1}^\top + \mathbf{x}_{a_K} \mathbf{x}_{a_K}^\top \right) \mathbb{P} \left\{ \mathbf{x}_{a_i}^\top \mathbf{w} < \cdots < \mathbf{x}_{a_K}^\top \mathbf{w} \right\} \right].
\]

Parameter \( \nu \) characterizes the skewness of the arms distribution \( p \), and it takes value 1 when considering symmetrical distributions. Notice that Assumption 2 is satisfied for a large class of distributions both discrete and continuous (e.g. Gaussian, multi-dimensional uniform and Rademacher). The value \( \omega_X \) depends on the arms distribution \( p \), the more positive the correlation among arms, the smaller \( \omega_X \). The extreme case is given by perfectly correlated arms, in that case we have \( \omega_X \) independent of any problem parameters. Finally, when arms are generated i.i.d. from a multivariate Gaussian or a multivariate uniform distribution over the sphere we have \( \omega_X = O(1) \).
2.2 Low-Rank Linear Contextual Bandits

In this paper we address the problem of simultaneously solving $T$ linear contextual bandit tasks. Each task $t \in [T]$ lasts for $N$ rounds and is associated with a regression vector $w_t \in \mathbb{R}^d$. We denote with 

$$W = [w_1, \ldots, w_T]$$

the $d \times T$ matrix, whose columns are formed by the $T$ unknown regression vectors. At each round $n \in [N]$ we face each task sequentially from the first up to the last. We are given the decision set $D_{t,n}$ associated with the $t$-th task at the $n$-th interaction from which the learning policy $\pi$ picks arm $x_{t,n}$ and subsequently, the associated feedback $y_{t,n}$ is observed via the linear regression

$$Y_{t,n} = x_{t,n}^\top w_t + \eta_{t,n}$$

where $\eta_{t,n}$ is a noise random variable which we specify below. Only when the reward is observed the protocol moves to the next task $t + 1$.

We make the following assumption on the task regression vectors.

**Assumption 3** (Low-Rank Assumption). The matrix $W \in \mathbb{R}^{d \times T}$ has rank $\rho(W) = r$, with $r \ll \min(d, T)$.

The above assumption implies that there exists an orthogonal matrix $Q \in \mathbb{O}^d$ that induces an alternative representation $A \in \mathbb{R}^{d \times T}$ such that $W = QA$. Defining $J(A) = \sum_{j=1}^d \|A[j]\|_F$, we assume matrix $A$ to satisfy $J(A) = r$. In agreement with (Argyriou et al., 2008), this means that the different tasks share a “small” set of features, hence, matrix $A$ has “many” rows which are identically equal to zero. This means either that the task weights or the features weights are correlated. The former case translates into having a small basis of tasks which are able to reproduce all the others. The latter represents the standard high-dimensional setting where many features are indeed redundant.

Our main learning objective is to minimize the multi-task pseudo-regret,

$$R(T,N) = \sum_{t=1}^T R(N, w_t) = \sum_{t=1}^T \sum_{n=1}^N (x^{*}_{t,n} - x_{t,n})^\top w_t$$

where $x^{*}_{t,n} = \arg \max_{x \in D_{t,n}} x^\top w_t$.

3 Low-Rank Matrix Estimation

In the standard supervised learning setting a natural estimator suited to Assumption 3 is given by the trace (nuclear) norm regularized estimator, see (Bühlmann and Van De Geer, 2011; Negahban and Wainwright, 2011) and references therein. In particular a large body of works have shown that bounds on the estimation error is controlled by the rank of the underlying regression matrix. Here we adapt this methodology to the bandit setting. At each round $n \in [N]$, we estimate matrix $W$ via $\hat{W}_{n+1}$ as the solution of the following trace norm regularization problem

$$\arg \min_{W \in \mathbb{R}^{d \times T}} \frac{1}{n} \sum_{t=1}^T \|y_{t,n} - X_{t,n} W[t]\|_2^2 + \lambda_n \|W\|_*$$

where the design matrix $X_{t,n} \in \mathbb{R}^{n \times d}$ contains the context vectors $x_{t,i} \in \mathbb{R}^d$, $i \in [n]$ as its rows, the vector $y_{t,n} \in \mathbb{R}^n$ is formed by the rewards for task $t$ after $n$ interactions, sampled from (2), and $\|W\|_*$ is the trace norm of the matrix $W$. If compared to the Lasso estimator, the objective function (4) encourages low-rank matrices instead of sparse vectors. Before moving with the technical results we need to introduce the following additional notation.
**Covariance matrices.** We indicate the theoretical \(d \times d\) covariance matrix as

\[
\Sigma = \frac{1}{K} \mathbb{E} \left[ \sum_{k=1}^{K} x_k x_k^T \right] = \frac{1}{K} \sum_{k=1}^{K} \Sigma_k,
\]

where the expectation is over the decision set sampling distribution \(p_X\) which is assumed to be shared between the tasks. For every \(t \in [T]\), we denote the empirical covariance matrix for task \(t\) as

\[
\hat{\Sigma}_{t,n} = \frac{1}{n} \sum_{s=1}^{n} x_{t,s} x_{t,s}^T
\]

and the corresponding adapted covariance matrix as

\[
\Sigma_{t,n} = \frac{1}{n} \sum_{s=1}^{n} \mathbb{E} \left[ x_{t,s} x_{t,s}^T x_{t,1}, Y_{t,1}, \ldots, Y_{t,s-1} \right].
\]

Moreover, we use the notation \(\Sigma, \hat{\Sigma}_{n}, \Sigma_{n}, \Sigma_{T,n} \in \mathbb{R}^{dT \times dT}\) for the theoretical, the empirical and the adapted multi-task matrices, respectively. They are all block diagonal and composed by the corresponding \(T\) single task \(d \times d\) matrices on the diagonal (e.g. \(\Sigma_{n} = \text{diag}(\Sigma_{1,n}, \ldots, \Sigma_{T,n})\)).

We introduce now the restricted strong convexity (RSC) condition, which allows us to control the error \(\Delta_n = \hat{W}_n - W\). This requires the considered loss function to be strictly convex under a restricted set of directions. The form we consider here will allow us to control the error of the estimator when the data are not constrained to be statistically independent.

**Definition 1 (RSC Condition).** Let \(W = UDV^T\) be the singular value decomposition of matrix \(W\) of rank \(r\), and let \(U^r\) and \(V^r\) be the submatrices formed by the top \(r\) left and right singular vectors, respectively. We say that the restricted strong convexity (RSC) condition is met for the theoretical multi-task matrix \(\Sigma \in \mathbb{R}^{dT \times dT}\), with positive constant \(\kappa(\Sigma)\) if

\[
\min \left\{ \frac{\|\text{Vec}(\Delta)\|_2^2}{2 \|\text{Vec}(\Delta)\|_2} : \Delta \in C(r) \right\} \geq \kappa(\Sigma).
\]

We used \(\text{Vec}(\Delta)\) for the \(\mathbb{R}^{dT}\) vector obtained by stacking together the columns of \(\Delta\), and \(C(r)\) is defined as

\[
\left\{ \Delta \in \mathbb{R}^{dT} : \|\Pi(\Delta)\|_* \leq 3 \|\Delta - \Pi(\Delta)\|_* \right\},
\]

where \(\Pi(\Delta)\) is the projection operator onto set \(B := \{ \Delta \in \mathbb{R}^{dT} : \text{Row}(\Delta) \perp U^r, \text{Col}(\Delta) \perp V^r\}\).

**Remark 1 (Value of \(\kappa(\Sigma)\)).** As discussed in (Calandriello et al., 2014) Definition 1 can be compared with the restricted eigenvalue and the compatibility conditions that have been investigated for the group Lasso (Bühlmann and Van De Geer, 2011; Lounici et al., 2011) and Lasso (Oh et al., 2021; Kim and Paik, 2019; Calandriello et al., 2014) estimators. More importantly, we want to highlight that \(\kappa(\Sigma)\) does not depend on \(d, T, n\). Indeed, \(\lambda_{\text{min}}(\Sigma) = \lambda_{\text{min}}(\Sigma)\), with \(\Sigma\) in (5), which is independent of \(T\). Finally, assuming \(\lambda_{\text{min}}(\Sigma) > 0\) and independent of \(d\), \(n\) is standard in compressed sensing. This argument also applies for the sparse bandit setting in (Bastani and Bayati, 2020). However if one assumes \(\|x\|_2 \leq b\), the restricted strong convexity parameter would depend on \(d\). For instance, if we consider the uniform distribution over the sphere we would have \(\kappa(\Sigma) = 1/d\). Notice that this oversight is present in many works in the literature which do not properly discuss the value of \(\kappa(\Sigma)\) (Oh et al., 2021; Cella and Pontil, 2021; Kim and Paik, 2019; Calandriello et al., 2014). Hence, all their bounds hide an additional dependency on the number of input features \(d\).
3.1 Oracle Inequality with non i.i.d. Data

We can now state our first result which controls the norm of the error
\[ \Delta_{n+1} = \hat{W}_{n+1} - W \]
assuming the RSC condition to hold for the empirical multi-task matrix \( \hat{\Sigma}_n \). In Section 4 we will show that such condition is satisfied with high probability under our Assumptions 1, 2 and 3.

**Lemma 1.** Let \( \{x_{t,i} : t \in [T], i \in [N]\} \) be the sequence generated by the policy (4) adapted sequence such that \( x_{t,s} \) may depend on \( \{x_{\tau,i} : \tau \leq t, i \leq s\} \). Suppose the restricted strong convexity condition holds for the empirical multi-task matrix \( \hat{\Sigma}_n \) defined earlier, with constant \( \kappa(\hat{\Sigma}_n) \). For \( \delta \in (0, 1) \), defining the regularization parameter
\[
\lambda_n \geq \frac{1}{n} \left\| \sum_{t=1}^{T} \sum_{i=1}^{n} x_{t,i} e_t^\top \eta_{t,i} \right\|_{\text{op}}.
\]
(9)

Then with probability at least \( 1 - \delta \) the trace-norm regularized estimate \( \hat{W}_n \) defined in (4) satisfies
\[
\left\| \hat{W}_{n+1} - W \right\|_F \leq \frac{32\lambda_n \sqrt{T}}{\kappa(\hat{\Sigma}_n)}.
\]
(10)

The proof, which is presented in the appendix, follows along the lines of (Negahban and Wainwright, 2011, Theorem 1). We alow note that a similar result can be also found in Koltchinskii et al. (2011).

3.2 Controlling the Noise Term

The result in Lemma 1 requires us to set the regularization parameter at round \( n \) as in (9). We have then to upper bound the operator norm of the following matrix
\[
D_n = \sum_{t=1}^{T} \sum_{i=1}^{n} \eta_{t,i} x_{t,i} e_t^\top
\]
where \( e_t \in \mathbb{R}^T \) is a column indicator vector.

Let us define the filtration \( (\mathcal{F}_n)_{n \geq 0} \) on a probability space \( (\Omega, \mathcal{A}, \mathbb{P}) \) as follows: \( \mathcal{F}_0 \) is the trivial \( \sigma \)-field \( \{\emptyset, \Omega\} \), and for any \( n \geq 1 \),
\[
\mathcal{F}_n = \sigma(X_{1,n}, \eta_{1,n}, \ldots, X_{T,n}, \eta_{T,n}).
\]

We consider the standard noise assumption Abbasi-Yadkori et al. (2011); Bastani and Bayati (2020); Cella et al. (2020).

**Assumption 4** (subGaussian noise). The noise variables \( (\eta_{t,n})_{t,n} \) are a sequence of subGaussian random variables adapted to the filtration \( \{\mathcal{F}_n\}_{n \geq 0} \) and such that for any \( 1 \leq t \leq T \) and \( n \geq 1 \),
\[
\mathbb{E}[\eta_{t,n} | \mathcal{F}_{n-1}] = 0, \quad \text{and} \quad \mathbb{E}[\eta_{t,n}^2 | \mathcal{F}_{n-1}] \leq \sigma^2,
\]
and \( \eta_{1,n}, \ldots, \eta_{T,n} \) are mutually independent conditionally on \( \mathcal{F}_{n-1} \). We denote by \( c_\eta \) the subGaussian norm of the \( \eta_{t,n} \)'s, that is, \( \max_{t,n} \left\{ \|\eta_{t,n}\|_{\psi_2} \right\} \leq c_\eta \).
Algorithm 1 Trace-Norm Bandit

Require: Confidence parameter \( \delta \), noise variance \( \sigma^2 \)

1: At round \( n = 1 \) arms are picked randomly
2: Observe \( Y_{1,1}, \ldots, Y_{T,1} \)
3: for \( n \in \{2, \ldots, N\} \) do
   4: update \( \hat{W}_n \) and \( \lambda_n \) according to (4) and (11)
   5: for \( t \in \{1, \ldots, T\} \) do
      6: observe \( D_{t,n} \)
      7: pick \( x_{t,n} \in \arg\max_{x \in D_{t,n}} x^\top [\hat{W}_n]_t \)
      8: observe reward \( Y_{t,n} \)
   9: end for
10: end for

Proposition 1 (SubGaussian noise). Let Assumptions 1 and 4 be satisfied. Then, with probability at least \( 1 - \delta \)
\[ \frac{1}{n} \|D_n\|_{\text{op}} \leq \lambda_n \]
where
\[ \frac{1}{n} \|D_n\|_{\text{op}} \leq 2\sqrt{2\epsilon_0 C_x} \left( \frac{T + d}{n} + \frac{\log(2\delta^{-1})}{n} \right) \]
\[ \sqrt{\sigma} \max_{1 \leq k \leq K} \left\{ \|\Sigma_k\|_{\text{op}}^{1/2} \right\} \left( \sqrt{\frac{T + d}{n}} + \sqrt{\frac{\log(2\delta^{-1})}{n}} \right) \] (11)

Proof. The complete proof is given in Appendix B. Here is a short sketch. The first step is a standard \( \epsilon \)-net approximation of \( \|D_n\|_{\text{op}} \). We have
\[ \|D_n\|_{\text{op}} = \max_{u \in \mathcal{S}^d, v \in \mathcal{S}^T} \{\langle D_n v, u \rangle\} \]
\[ \leq 2 \max_{u \in \mathcal{N}, v \in \mathcal{M}} \{\langle D_n v, u \rangle\} , \]
where \( \mathcal{N} \) and \( \mathcal{M} \) are finite \( 1/4 \)-nets of unit balls \( \mathcal{S}^d \) and \( \mathcal{S}^T \) respectively. Next, for fixed \( u \in \mathcal{N}, v \in \mathcal{M} \), we prove that the random process \( \{\langle D_n v, u \rangle\}_n \) is a \( \{\tilde{F}_n\}_n \)-martingale with finite quadratic increments so that we can apply a version of Bernstein’s deviation inequality for martingales (Bercu et al., 2015, Theorem 3.14) combined with an union bound argument to get the result.

4 Multi-Task Bandits via Trace Norm Regularization

In this section we present our proposed algorithm for multitask learning with linear stochastic bandits.

The algorithm relies on the nuclear norm regularized estimator in (4) and is displayed in Algorithm 1. It does not require to know any input parameter besides the confidence value \( \delta \) and the variance of the noise \( \sigma^2 \). Similarly to (Oh et al., 2021) it does not need any forced-sampling strategy. At each round, it updates the tasks parameters via a trace-norm regularized estimation using all the already observed data.

In order to bound the regret, at each round \( n \in [N] \), we need to control the multi-task theoretical matrix \( \Sigma \) with the multi-task adapted one \( \hat{\Sigma}_n \). This allows matrix \( \hat{\Sigma}_n \) to satisfy the RSC Condition, hence to meet rates as in (10).

8
4.1 Multi-Task Learning

In this subsection we upper bound the multi-task regret incurred by the proposed policy. The proof we present here is inspired by the one proposed in (Oh et al., 2021) for the single task lasso bandit approach. In order to prove the regret bound we first need to introduce the following technical lemmas.

The first lemma gives a high probability bound on the deviation of $\hat{\Sigma}_n$ from $\Sigma_n$ according to the operator norm. Recall that we denote by $\Sigma_k$ the $d \times d$ covariance operator of the $k$-th arm.

**Lemma 2 (Operator norm Concentration).** Let Assumption 1 be satisfied. For any $n \geq 1$ and $x > 0$, with probability at least $1 - e^{-x}$ we get for all $x > 0$, with probability at least $1 - e^{-x}$

$$\left\| \hat{\Sigma}_n - \Sigma_n \right\|_{op} \leq C \left( \frac{b^2 d (x + \log(dT))}{n} \sqrt{\max_{1 \leq k \leq K} \left\{ \left\| \Sigma_k \right\|_{op} \right\} \sqrt{\frac{1}{n}} \sqrt{\frac{b^2 d (x + \log(dT))}{n}} \right)$$

(12)

for some absolute constant $C > 0$.

**Proof.** The proof can be found in the appendix material. It relies on the Freedman’s inequality for matrix-valued martingales (see Oliveira, 2010, Theorem 1.2). \qed

The next lemma guarantees that if the operator norm distance between two matrices is small enough and if one of these two matrices satisfies the RSC condition, then the other matrix also satisfied the RSC condition. Specifically, the next lemma links the RSC constant $\kappa(\Sigma)$ associated to the multi-task theoretical matrix, to the adapted one $\kappa(\hat{\Sigma}_n)$.

**Lemma 3 (RSC condition and Random Matrices).** Let $\Sigma_0$ and $\Sigma_1$ be two $dT \times dT$ block-diagonal matrices (with blocks matrices of size $d \times d$). Suppose that the RSC condition is met for the covariance matrix $\Sigma_0$ with constant $\kappa(\Sigma_0)$ and that $\left\| \Sigma_0 - \Sigma_1 \right\|_{op} \leq \tilde{\lambda}$, where

$$\tilde{\lambda} \leq \kappa(\Sigma_0)/2.$$

Then, the RSC condition is also met for the covariance matrix $\Sigma_1$ with constant $\kappa(\Sigma_1) \geq \kappa(\Sigma_0)/2$. Moreover, for all $\Delta \in \mathbb{R}^{dT \times T}$ such that $\Delta \in C(r)$ (see Equation 8), we have

$$\|\text{Vec}(\Delta)\|_{\Sigma_0}^2 \leq 2 \|\text{Vec}(\Delta)\|_{\Sigma_1}^2 \leq 3 \|\text{Vec}(\Delta)\|_{\Sigma_0}^2.$$

(13)

**Proof.** The proof is a combination of the RSC Definition 1 and the operator-norm closeness $\left\| \Sigma_0 - \Sigma_1 \right\|_{op} \leq \tilde{\lambda}$. \qed

The last technical result we need before proving the regret bound concerns the control of the number of rounds we need to wait before having the RSC to hold.

For fixed $x > 0$, define $N_0$ as

$$\left( \frac{\nu \omega_X \sum_{k=1}^K \left\| \Sigma_k \right\|_{op}}{\kappa(\Sigma)} \sqrt{1} \right) \frac{C' b^2 d \nu \omega_X (x + \log(dT)) \kappa(\Sigma)}{\kappa(\Sigma)}$$

(14)

for some large enough absolute constant $C' > 0$. 9
Lemma 4. Let the assumptions of Lemmas 2 and 3 be satisfied. Then, for any $x > 0$ and any $n \geq N_0$, with probability at least $1 - e^{-x}$, the multi-task empirical matrix $\hat{\Sigma}_n$ satisfies the RSC condition with constant 

$$\kappa(\hat{\Sigma}_n) \geq \frac{\kappa(\Sigma)}{4\nu \omega X} > 0.$$ 

Proof. In the RSC condition (see Definition 1) the considered covariance matrix $\Sigma \in \mathbb{R}^{dT \times dT}$ is block-diagonal consisting of $T$ blocks, one for each different task. Let us consider now the single-task adapted matrix

$$\Sigma_{t,n} = \frac{1}{n} \sum_{s=1}^{n} \mathbb{E} [x_{t,s} x_{t,s}^\top | F_{s-1}]$$

and the multi-task one $\Sigma_n = \text{diag}(\Sigma_{1,n}, \ldots, \Sigma_{T,n}) \in \mathbb{R}^{dT \times dT}$. Relying on (Oh et al., 2021, Lemma 10), under Assumption 2 we have

$$\Sigma_n = \frac{1}{n} \sum_{s=1}^{n} \mathbb{E} [x_s x_s^\top | F_{s-1}] \succeq (2\nu \omega X)^{-1} \Sigma,$$ 

where $x_s = [x_{1,s}^\top, \ldots, x_{T,s}^\top]^\top \in \mathbb{R}^{dT}$. Now, let us denote

$$\tilde{w}_n = \arg \min_{\tilde{w} \in C(r)} \frac{\tilde{w} \Sigma_n \tilde{w}}{\|\tilde{w}\|_2^2}.$$

Relying on the RSC condition and thanks to the previous display, we obtain

$$\frac{\tilde{w}_n^\top \Sigma_n \tilde{w}_n}{\|\tilde{w}_n\|_2^2} \geq \frac{\tilde{w}_n^\top \Sigma \tilde{w}_n}{2\nu \omega X \|\tilde{w}_n\|_2^2} \geq \frac{\kappa(\Sigma)}{2\nu \omega X}.$$

Hence, $\Sigma_n$ satisfies the RSC condition with constant 

$$\kappa(\Sigma_n) = \frac{\kappa(\Sigma)}{2\nu \omega X}.$$

We now consider the multi-task adapted matrix $\Sigma_0 = \Sigma_n$ and the multi-task empirical matrix $\hat{\Sigma}_1 = \hat{\Sigma}_n$. In view of Lemma 2, if $n \geq N_0$ then with probability at least $1 - e^{-x}$,

$$\|\hat{\Sigma}_n - \Sigma_n\|_{op} \leq \frac{\kappa(\Sigma)}{4\nu \omega X} \leq \frac{\kappa(\Sigma_n)}{2\nu \omega X}.$$

Then Lemma 3 yields the result. 

Now we are ready to prove an high probability bound to the multi-task regret $\mathcal{R}(T, N)$.

Theorem 1. Let Assumptions 1, 2, 3, 4 be satisfied. Then, for any $\delta \in (0, 1)$, with probability at least $1 - \delta$, the multi-task regret of Algorithm 1 is upper bounded as

$$\mathcal{O} \left( \sqrt{NdT (\sqrt{(T + d)} \sqrt{\log(2N\delta^{-1})})} \right).$$
Sketch of the proof. The proof consists of a combination of the previously introduced lemmas. Building on Lemma 4 during the first \(N_0\) rounds the RSC condition would not hold, the same is true for the convergence result of Lemma 1. During those trials we will then consider the maximal regret per round of \(2LTb\). We can then focus to the rounds \(n > N_0\). Specifically, according on Lemma 2 and 3 the RSC would be met for the multi-task empirical matrix \(\hat{\Sigma}_n\), with probability \(1 - \delta\). Hence, we can then rely on the nuclear-norm oracle inequality of Lemma 1. Considering the bound of the mentioned lemma and summing over the \(N\) trials gives the regret leading factor of \(O(\sqrt{NdT\tau(T + d)})\).

Result Discussion. Notice that running any \(T\) independent policies (ITL) with the linear contextual bandit setting defined in Section 2.1 under Assumptions 1, 2 would yield a regret bound of order \(Td\sqrt{N}\). This can be shown considering the lower bound argument in (Lattimore and Szepesvári, 2020, See Chapter 24.1). Since this lower bound is always larger than the upper bound in Theorem 1 for the proposed MTL method, there is a gain in using our method. In particular, if \(T > d\), discarding logarithmic factors, the bound for our method is smaller by a factor of order \(O(\sqrt{d/r})\), while for \(d > T\) the gain is of order \(O(\sqrt{T/r})\).

5 Multi-Task Lower Bound

In this last section we provide a lower bound argument to the multi-task regret we defined in Equation 3.

**Theorem 2.** Let us consider the sparse represented multi-task setting described in Section 2.2. Let the tasks to satisfy Assumptions 1-4. Then, considering \(TN \geq rd\) the multi-task regret in Equation 3 satisfies the following lower bound

\[
\overline{R}(T, N) \geq \Theta \left( \sqrt{TNd} \right). \tag{16}
\]

**Proof sketch.** The proof considers a specific instance achieving the mentioned lower bound. We consider \(T = r\) tasks, with \(T + r\) dimensional vector parameters. The last \(r\) variables are only necessary to set the rank value in Assumption 3 equal to \(r\).

We consider \(K = r\) arms, each of which is associated to a different orthonormal base generating a non-singular covariance matrix. The set of arms is such that only the first \(r\) variables effectively correlates with the reward random variable. Specifically, we uniformly pick one arm whose expected reward differs from all the other by a factor \(\sqrt{rd/TN}\).

The lower bound then follows using a similar reasoning to the one adopted in Auer et al. (2002).

The above lower bound matches the upper bound of Theorem 1 up to a factor \(\sqrt{d + T}\). Building on the previous argument, we add an additional lower-bound result which refers to the high-dimensional single-task setting (Oh et al., 2021; Kim and Paik, 2019; Bastani and Bayati, 2020).

**Remark 2.** We notice that the proof of Theorem 2 can be directly adapted to the simpler sparse linear setting (Oh et al., 2021). This would yield a lower bound of \(\sqrt{sN}\) under the restricted-eigenvalue (RE) conditions when considering \(N \geq s\).

**Sketch of the proof.** In this proof we consider a specific learning instance with \(d = 2s\). The regression vector \(w \in \mathbb{R}^d\) has value 1 for the first \(s\) components and 0 for the remaining ones. Similarly to the proof of Theorem 2, we associate each context to one orthonormal basis. Their definition is such that, all arms expected rewards are \(\frac{1}{2}\) but one, which is chosen uniformly over the set of arms, whose expected reward is \(\frac{1}{2} + \frac{1}{4}\sqrt{sN}\). As we did for Theorem 2, the proof concludes by lower bounding the pseudo-regret relying on (Auer et al., 2002, Lemma A.1).
This remark answers an open question about the optimality of the solution proposed in (Oh et al., 2021, see Theorem 2). A full proof of this remark is presented in the appendix.

6 Experiments

In this section we validate the policy proposed in Section 4 by considering the multi-task setting.

The experiments displayed in Figure 1 and 2 compare three different policies: OFUL (Abbasi-Yadkori et al., 2011), the Trace-Norm Bandit approach of Algorithm 1 and the Random policy which randomly selects the arm to play. In order to compute the trace-norm estimator (equation 4) we adopt the accelerated gradient method proposed in (Ji and Ye, 2009). All policy parameters have been accurately validated over a logarithmic scale. Interestingly, greater sensitivity to the regularization parameter occurs considering OFUL (Abbasi-Yadkori et al., 2011). Finally, we adopted the cumulative reward gathered overall tasks as performance metric. All the experiments refer to the average of 10 repetitions. Specific values of average cumulative rewards with theirs standard deviations can be found in Section H of the appendix.

Data Processing. We conduct numerical experiments on different configurations. Each of which is characterized by size of arm sets $K$, number of rounds $N$ and context size $d$. As metric we consider the cumulative reward as a function of the number of tasks. The arm set is shared among tasks and generated randomly from a Gaussian distribution with random covariance. The set of task vectors $\mathbf{w}_1, \ldots, \mathbf{w}_T$ has been chosen to be jointly-sparse with sparsity $r$. Both, the set of relevant features and the respective task vectors has been chosen randomly from a standard Gaussian.

Result Discussion. Although preliminary, the experimental results displayed in Figures 1 and 2, indicate an advantage in using the multi-task approach when Assumption 3 is met. The comparison with the Random policy only confirms the non triviality of the considered learning setting.
7 Limitations and Future Work

In this work we have studied the benefit of multi-task representation learning in the setting of linear contextual bandit tasks. We proposed a novel bandit policy based on trace-norm regularization which is computationally efficient and does not need knowledge of the rank of the underlying task matrix. We derived an upper bound for the multi-task regret of the proposed policy, showing that it is effective in comparison to learning the tasks independently. We also presented a nearly matching lower bound and encouraging preliminary experiments.

In this work we have restricted our analysis to the case of linear feature learning. Additionally, we still require the designed policy to know one problem parameter which is the variance associated to the noisy term. Relying on (Maurer et al., 2016), in the future an interesting extension would be to go beyond the linearity of the shared representation. Secondly, inspired by (Belloni et al., 2011) a challenge one may try to solve is to design a fully parameter free policy. Namely, a policy which does not require to know the noise variance $\sigma^2$. Finally an important direction is to extend the analysis presented here to the meta-learning setting, in which the tasks are observed sequentially and the goal is to minimize the regret on future yet-unseen tasks.

References

Appendix

This appendix provides full proofs of the results stated in the main body of the paper. It is organized as follows:

- Appendix A contains the proof of Lemma 1, which is the oracle inequality associated to the error $\Delta_{n+1} = \hat{W}_{n+1} - W$ considering non i.i.d. data.

- Appendix B refers to one of the most pivotal result of Appendix 3, notably the bound to the trace norm of matrix $D_n = \sum_{t=1}^{T} \sum_{i=1}^{n} \eta_{t,i} x_{t,i} \otimes e_t$.

- Appendices C and D contains the proofs of Lemmas 2 and 3, respectively. These results allow us to connect the RSC constant $\kappa(\Sigma)$ associated to the theoretical covariance $\Sigma \in \mathbb{R}^{d \times d}$ to its empirical counterpart $\kappa(\hat{\Sigma}_n)$.

- Appendix E contains the proof for the regret upper bound associated to the policy of Alg. 1.
In Appendix F we prove the multi-task regret lower bound. Similarly, in Appendix G we give the proof of the regret lower bound relative to the high-dimensional single-task setting (Oh et al., 2021).

Finally, in Appendix H we give more details on our numerical experiments.

The following table summarizes the main notation used throughout the paper.

## A Proof of Lemma 1

By definition of $\hat{W}_n$, we have for any $W \in \mathbb{R}^{d \times T}$,

$$
\frac{1}{n} \sum_{t=1}^{T} \left\| y_{t,n} - X_{t,n}[\hat{W}_{n+1}]_{t} \right\|_2^2 + \lambda_n \left\| \hat{W}_{n+1} \right\|_* \leq \frac{1}{n} \sum_{t=1}^{T} \left\| y_{t,n} - X_{t,n}[W]_t \right\|_2^2 + \lambda_n \left\| W \right\|_* .
$$

</table>
We define the error matrix $\Delta_{n+1} = \hat{W}_{n+1} - W$ and introduce the following operator $\mathcal{A} : \mathbb{R}^{d \times T} \rightarrow \mathbb{R}^{n \times T}$ and its adjoint $\mathcal{A}^* : \mathbb{R}^{n \times T} \rightarrow \mathbb{R}^{d \times T}$ as

$$[\mathcal{A}(W)]^t_n = \langle x_{t,n}e^T_t, W \rangle = \text{Tr}(W e_t x_{t,n}) = x^T_{t,n}w_t$$

$$\mathcal{A}^*(\eta_{t,n}) = \sum_{t=1}^T \sum_{i=1}^n x_{t,i}^T \eta_{t,s} = D_n \in \mathbb{R}^{d \times T}.$$ 

Using this notation the following hold

$$\frac{1}{n} \|\mathcal{A}(\Delta_{n+1})\|^2_F = \frac{1}{n} \sum_{t=1}^T \| [\mathcal{A}(\Delta_{n+1})]^t \|^2 \leq \frac{1}{n} \langle \eta_n, \mathcal{A}(\Delta_{n+1}) \rangle + \lambda_n \left( \|W\|_* - \|\hat{W}_{n+1}\|_* \right)$$

$$\leq \frac{1}{n} \langle \eta_n, \mathcal{A}(\Delta_{n+1}) \rangle + \lambda_n \left( \|\hat{W}_{n+1} + \Delta_{n+1}\|_* - \|\hat{W}_{n+1}\|_* \right)$$

$$\leq \frac{1}{n} \langle \eta_n, \mathcal{A}(\Delta_{n+1}) \rangle + \lambda_n (\|\Delta_{n+1}\|_*).$$

Considering now the first term on the RHS and applying Holder’s inequality we have

$$\frac{1}{n} |\langle \eta_n, \mathcal{A}(\Delta_{n+1}) \rangle| = \frac{1}{n} |\langle \mathcal{A}^*(\eta_n), \Delta_{n+1} \rangle| \leq \frac{1}{n} \|\mathcal{A}^*(\eta_n)\|_{\text{op}} \|\Delta_{n+1}\|_*.$$

Now, considering $\lambda_n \geq \frac{1}{n} \|\mathcal{A}^*(\eta_n)\|_{\text{op}}$ the following holds:

$$\frac{1}{n} \|\mathcal{A}(\Delta_{n+1})\|^2_F \leq 2 \lambda_n \|\Delta_{n+1}\|_*.$$

Relying on Negahban and Wainwright (2011)[Lemma 1] we can decompose the error matrix $\Delta_{n+1}$ as $\Delta'_{n+1} + \Delta''_{n+1}$ satisfying

$$\|\Delta_{n+1}\|_* \leq 4 \|\Delta'_{n+1}\|_*.$$  

(18)

Assuming the RSC condition to be met with constant $\kappa(\hat{\Sigma}_n)$, starting from Equation 17 we get

$$\|\Delta_{n+1}\|^2_F \leq \frac{\|\mathcal{A}(\Delta_{n+1})\|^2_F}{2n\kappa(\hat{\Sigma}_n)} \leq \frac{\lambda_n \|\Delta_{n+1}\|_*}{\kappa(\hat{\Sigma}_n)}.$$

These last two results combined with Negahban and Wainwright (2011)[Lemma 1] give that $\|\Delta'_{n+1}\|_* \leq \sqrt{2\tau} \|\Delta'_{n+1}\|_F$, from which we conclude that

$$\|\Delta_{n+1}\|_F \leq \frac{32 \lambda_n \sqrt{\tau}}{\kappa(\hat{\Sigma}_n)}.$$

### B Proof of Proposition 1

The following technical lemma is an immediate consequence of well-known properties of subGaussian random variables. See for instance Lemma 5.5 in Vershynin (2010).
Lemma 5. Let $Z$ be a subGaussian random variable with zero mean and variance $\sigma^2$. For any $p \geq 3$, we have

$$E[|Z|^p] \leq \sqrt{e(p-2)!} \|Z\|_{\psi_2}^{p-2} \sigma^2.$$  

Proof. For any $p \geq 3$, we have by Cauchy-Schwartz and Jensen’s inequalities

$$E[|Z|^p] \leq E[|Z|^{2(p-2)}]E[|Z|^4] \leq E[Z^{2(p-2)}]E[Z^2] = E[Z^{2(p-2)}] \sigma^2. \quad (19)$$

The following argument appears in the proof of Lemma 5.5 in Vershynin (2010). By definition of subGaussian random variable $Z$, we have for any $t > 0$,

$$P(|Z| \geq \|Z\|_{\psi_2} t) \leq e^{1-t^2}. \quad (20)$$

where we have used the well-known property of the Gamma function $\Gamma(m) = (m-1)!$ for any integer $m \geq 1$. Combining the previous display with (19) gives the result. \qed

We can now move to the main proof. Let us define

$$D_n := \sum_{t=1}^T \sum_{i=1}^n x_{t,i}^T e_t \eta_{t,i} \in \mathbb{R}^{d \times T}. \quad (21)$$

The first step of the proof is a standard $\epsilon$-net approximation argument. We have

$$\|D_n\|_{op} = \max_{u \in S^d, v \in S^T} \{ \langle D_n v, u \rangle \}. \quad (22)$$

Fix $\epsilon \in (0, 1/2)$. An $\epsilon$-net $\mathcal{N}_\epsilon$ of $S^m$ is a subset of $S^m$ such that for any $u \in S^m$, there exists $v \in \mathcal{N}_\epsilon$ such that $\|u - v\| \leq \epsilon$. Corollary 4.2.13 in Vershynin (2018) guarantees the existence of an $\epsilon$-net $\mathcal{N}_\epsilon$ of $S^d$ and an $\epsilon$-net $M_\epsilon$ of $S^T$ such that

$$|\mathcal{N}_\epsilon| \leq \left(1 + \frac{2}{\epsilon}\right)^d, \quad |M_\epsilon| \leq \left(1 + \frac{2}{\epsilon}\right)^T. \quad (23)$$

Similarly to the first step of the proof of Theorem 4.4.5 in Vershynin (2018), we get

$$\|D_n\|_{op} \leq \frac{1}{1 - 2\epsilon} \max_{u \in \mathcal{N}_\epsilon, v \in M_\epsilon} \{ \langle D_n v, u \rangle \}. \quad (24)$$

We now fix $u \in \mathcal{N}_\epsilon$, $v \in M_\epsilon$ and we study the deviations of $\langle D_n v, u \rangle$. We define $M_0 = 0$ a.s. and for any $n \geq 1$,

$$M_n := \langle D_n v, u \rangle = \sum_{t=1}^T \sum_{i=1}^n \langle u, x_{t,i} \rangle \langle e_t, v \rangle \eta_{t,i}. \quad (25)$$

19
By nature of the Trace-Norm bandit (Algorithm 1), given the $F_{n-1}$, we select at round $n$ the arms for the $T$ tasks: $x_{t,n} \in D_{t,n}$ with $D_{t,n}$ independent of $(\eta_{t,n})_{1 \leq t \leq T}$. This means that

$$(x_{t,n})_{1 \leq t \leq T} \perp (\eta_{t,n})_{1 \leq t \leq T} \mid F_{n-1}. \quad \text{(26)}$$

Consequently, under Assumption 1 and 4, $(M_n)_{n \geq 0}$ is a square-root integrable martingale adapted to the filtration $\{F_n\}_{n \geq 0}$. Define the corresponding increasing process by: $\langle M \rangle_0$ and for all $n \geq 1$

$$\langle M \rangle_n = \sum_{i=1}^{n} \mathbb{E} [ (M_i - M_{i-1})^2 \mid F_{i-1} ] . \quad \text{(24)}$$

Define for any $n \geq 1$

$$V_n := \mathbb{E} [ (M_n - M_{n-1})^2 \mid F_{n-1} ] . \quad \text{(25)}$$

Under Assumptions 1 and 4, we have for any $n \geq 1$

$$V_n = \mathbb{E} \left[ \left( \sum_{t=1}^{T} \langle u, x_{t,n} \rangle (e_t, v) \eta_{t,n} \right)^2 \mid F_{n-1} \right] = \mathbb{E} \left[ \sum_{t=1}^{T} (u, x_{t,n})^2 (e_t, v)^2 \eta_{t,n}^2 \mid F_{n-1} \right]$$

$$= \sum_{t=1}^{T} \mathbb{E} \left[ (u, x_{t,n})^2 \mid F_{n-1} \right] \langle e_t, v \rangle^2 \mathbb{E} \left[ \eta_{t,n}^2 \mid F_{n-1} \right]$$

$$\leq \sigma^2 \max_{1 \leq k \leq K} \left\{ \| \Sigma_k \|_{\text{op}} \right\}, \quad \text{(26)}$$

where we have used that $\mathbb{E}[\eta_{t,n}\eta_{t',n}\mid F_{n-1}] = 0$ for any distinct $t, t'$ and that $\sum_{t=1}^{T} \langle e_t, v \rangle^2 = \|v\|^2 = 1$.

**Fact 1.** We prove for any integer $p \geq 3$ and for all $1 \leq n \leq N$,

$$\mathbb{E} \left[ \| M_n - M_{n-1} \|_{F_{n-1}}^p \right] \leq \frac{p!}{2} \left( \sqrt{2} c_\eta C_\phi \right)^{p-2} \sigma^2, \quad \text{a.s.} \quad \text{(27)}$$

**Proof of Fact 1.** By tower property of conditional expectation, we have

$$\mathbb{E} \left[ \| M_n - M_{n-1} \|_{F_{n-1}}^p \right] = \mathbb{E} \left[ \mathbb{E} \left[ \| M_n - M_{n-1} \|_{F_{n-1}}^p \mid F_{n-1}, (x_{t,n})_{1 \leq t \leq T} \right] \mid F_{n-1} \right]$$

$$= \mathbb{E} \left[ \mathbb{E} \left[ \sum_{t=1}^{T} (u, x_{t,n}) (e_t, v) \eta_{t,n} \mid F_{n-1}, (x_{t,n})_{1 \leq t \leq T} \right] \mid F_{n-1} \right]. \quad \text{(28)}$$

Next, using property (4) in Lemma 5.5. in Vershynin (2010) in combination with Assumption 4, we get, conditionally on $F_{n-1}, (x_{t,n})_{1 \leq t \leq T}$ that $\sum_{t=1}^{T} (u, x_{t,n}) (e_t, v) \eta_{t,n}$ is subGaussian with Orlicz $\psi_2$-norm

$$\left\| \sum_{t=1}^{T} (u, x_{t,n}) (e_t, v) \eta_{t,n} \right\|_{\psi_2} \leq c_\eta \sqrt{\sum_{t=1}^{T} (u, x_{t,n})^2 (e_t, v)^2} =: c_n.$$
We compute now the conditional expectation
\[
E \left[ \left( \sum_{t=1}^T \langle u, x_{t,n} \rangle \langle e_t, v \rangle \eta_{t,n} \right)^p \bigg| \mathcal{F}_{n-1}, (x_{t,n})_{1 \leq t \leq T} \right]
\leq \sqrt{e(p - 2)!} \epsilon_n^{p-2} \sigma^2
\leq \sqrt{e(p - 2)!} \epsilon_n^{p-2} \left( \sum_{t=1}^T \langle u, x_{t,n} \rangle^2 \langle e_t, v \rangle^2 \right)^{\frac{p-2}{2}} \sigma^2, \ a.s.
\tag{29}
\]

Consequently, Lemma 5 gives for any \( p \geq 3 \)

\[
E \left[ \left( \sum_{t=1}^T \langle u, x_{t,n} \rangle \langle e_t, v \rangle \eta_{t,n} \right)^p \bigg| \mathcal{F}_{n-1}, (x_{t,n})_{1 \leq t \leq T} \right]
\leq \sqrt{e(p - 2)!} \epsilon_n^{p-2} \sigma^2
\leq \sqrt{e(p - 2)!} \epsilon_n^{p-2} \left( \sum_{t=1}^T \langle u, x_{t,n} \rangle^2 \langle e_t, v \rangle^2 \right)^{\frac{p-2}{2}} \sigma^2, \ a.s.
\tag{29}
\]

We compute now the conditional expectation
\[
E \left[ \left( \sum_{t=1}^T \langle u, x_{t,n} \rangle^2 \langle e_t, v \rangle^2 \right)^{\frac{p-2}{2}} \bigg| \mathcal{F}_{n-1} \right].
\]

We recall now some well-known properties of subGaussian and subexponential rvs (see Vershynin (2010) for more details). Since the \( x_{t,n} \) are subGaussian mutually independent rvs, the rvs \( \langle u, x_{t,n} \rangle \) are also subGaussian mutually independent with \( \|\langle u, x_{t,n} \rangle\|_{\psi_2} \leq \|x_{t,n}\|_{\psi_2} \) for any \( u \in \mathbb{S}^d \). Also, \( \langle u, x_{t,n} \rangle^2 \) is subexponential with \( \|\langle u, x_{t,n} \rangle\|^2_{\psi_1} \leq 2 \|\langle u, x_{t,n} \rangle\|^2_{\psi_2} \leq 2 \|x_{t,n}\|^2_{\psi_2} \leq 2C_x^2 \) in view of Assumption 1. By the independence condition, the sum \( \sum_{t=1}^T \langle u, x_{t,n} \rangle^2 \langle e_t, v \rangle^2 \) is subexponential with

\[
\left\| \sum_{t=1}^T \langle u, x_{t,n} \rangle^2 \langle e_t, v \rangle^2 \right\|_{\psi_2} \leq 2 \sum_{t=1}^T \|\langle u, x_{t,n} \rangle\|^2_{\psi_2} \leq 2 \|x_{1,n}\|^2_{\psi_2} \leq 2C_x^2, \ \forall u \in \mathbb{S}^d, \ v \in \mathbb{S}^T,
\]

where we have that \( \|x_{1,n}\|_{\psi_2} = \cdots = \|x_{T,n}\|_{\psi_2} \) in our multi-task setting.

The previous display and Lemma 5.14 in Vershynin (2010) gives that \( \sqrt{\sum_{t=1}^T \langle u, x_{t,n} \rangle^2 \langle e_t, v \rangle^2} \) is subGaussian with

\[
\left\| \sqrt{\sum_{t=1}^T \langle u, x_{t,n} \rangle^2 \langle e_t, v \rangle^2} \right\|^2_{\psi_2} \leq \left\| \sum_{t=1}^T \langle u, x_{t,n} \rangle^2 \langle e_t, v \rangle^2 \right\|_{\psi_1} \leq 2 \|x_{1,n}\|^2_{\psi_2} \leq 2C_x^2, \ \forall u \in \mathbb{S}^d, \ v \in \mathbb{S}^T.
\tag{30}
\]

Applying Lemma 5 again to \( Z = \left( \sum_{t=1}^T \langle u, x_{t,n} \rangle^2 \langle e_t, v \rangle^2 \right)^{\frac{1}{2}} \) gives for any \( p \geq 5 \)

\[
E \left[ \left( \sum_{t=1}^T \langle u, x_{t,n} \rangle^2 \langle e_t, v \rangle^2 \right)^{\frac{p-2}{2}} \bigg| \mathcal{F}_{n-1} \right] \leq \sqrt{e(p - 2)!} (\sqrt{2}\|x_{1,n}\|_{\psi_2})^{p-2} \leq \sqrt{e(p - 2)!} (\sqrt{2}C_x)^{p-2}.
\]

The previous inequality is also valid for \( p = 3 \) and \( p = 4 \) as it follows directly from the definition of a subgaussian random variable.

Combining the previous displays with (28),(29), we obtain for for any \( p \geq 3 \),

\[
E \left[ \left( \sum_{t=1}^T \langle u, x_{t,n} \rangle \langle e_t, v \rangle \eta_{t,n} \right)^p \bigg| \mathcal{F}_{n-1} \right] \leq e(p - 2)! \left( \sqrt{2}c_\eta C_x \right)^{p-2} \sigma^2 = \frac{p^p}{2} \left( \sqrt{2}c_\eta C_x \right)^{p-2} \sigma^2, \ a.s.
\]

\[\square\]
Set $\tilde{c} = \sqrt{2c_\eta C_\chi}$. In view of (27), Theorem 3.14 in Bercu et al. (2015) gives for any positive $t$, $s$, with probability at least $1 - e^{-nt}$,

$$\mathbb{P}\left( M_n > n(\tilde{c} t + \sqrt{2ts}), \langle M \rangle_n \leq ns \right) \leq \exp(-nt).$$

We study next the quadratic process $\langle M \rangle_n$. In view of (26), we immediately get

$$\langle M \rangle_n \leq \sigma^2 \max_{1 \leq k \leq K} \left\{ \| \Sigma_k \|_{op} \right\} n, \text{ a.s.}$$

We take $s = \sigma^2 \max_{1 \leq k \leq K} \left\{ \| \Sigma_k \|_{op} \right\}$ and $t' = nt$. Combining the last two displays gives with probability at least $1 - 2e^{-t'}$

$$|M_n| \leq \sqrt{2c_\eta C_\chi} t' + \sigma \max_{1 \leq k \leq K} \left\{ \| \Sigma_k \|_{op}^{1/2} \right\} \sqrt{2n t'}.$$  \hspace{1cm} (31)

We define now the event

$$\Omega_n = \bigcap_{u \in \mathcal{N}_t, v \in \mathcal{M}_t} \left\{ |(D_n v, u)| \leq \sqrt{2c_\eta C_\chi} t' + \sigma \max_{1 \leq k \leq K} \left\{ \| \Sigma_k \|_{op}^{1/2} \right\} \sqrt{2n t'} \right\}.$$ 

Set $\epsilon = 1/4$. A simple union bound gives in view of (22) and (31)

$$\mathbb{P}(\Omega_n^c) \leq |\mathcal{M}_t| |\mathcal{N}_t| e^{-t'} \leq 2e^{(d+T) \log(9) - t'}.$$ 

Now we set $t' = \log(2\delta^{-1}) + (T + d) \log(9)$ for some $\delta \in (0, 1)$. Consequently, we obtain that

$$\mathbb{P}(\Omega_n) \geq 1 - \delta.$$ 

It follows, in view of (23), with probability at least $1 - \delta$

$$\|D_n\|_{op} \leq 2\sqrt{2} \left( c_\eta C_\chi (\log(2\delta^{-1}) + (T + d) \log(9)) + \sigma \max_{1 \leq k \leq K} \left\{ \| \Sigma_k \|_{op}^{1/2}, \sqrt{n(\log(2\delta^{-1}) + (T + d) \log(9))} \right\} \right).$$

Consequently, we get with probability at least $1 - \delta$

$$\frac{1}{n} \|D_n\|_{op} \leq 2\sqrt{2} \left( \left[ c_\eta C_\chi \frac{T + d}{n} + c_\eta C_\chi \frac{\log(2\delta^{-1})}{n} \right] \right) \sqrt{\sigma \max_{1 \leq k \leq K} \left\{ \| \Sigma_k \|_{op}^{1/2}, \sqrt{\frac{(T + d)}{n}}, \sigma \max_{1 \leq k \leq K} \| \Sigma_k \|_{op}^{1/2}, \sqrt{\frac{(\log(2\delta^{-1})}{n})} \right\}}.$$ 

From Proposition 1 and an union bound, we immediately deduce, with probability at least $1 - \delta$,

$$\max_{1 \leq n \leq N} \frac{\|D_n\|_{op}}{n} \leq 2\sqrt{2} \left( \left[ c_\eta C_\chi \frac{T + d}{n} + c_\eta C_\chi \frac{\log(2N\delta^{-1})}{n} \right] \right) \sqrt{\sigma \max_{1 \leq k \leq K} \left\{ \| \Sigma_k \|_{op}^{1/2}, \sqrt{\frac{(T + d)}{n}}, \sigma \max_{1 \leq k \leq K} \| \Sigma_k \|_{op}^{1/2}, \sqrt{\frac{\log(2N\delta^{-1})}{n}} \right\}}.$$  \hspace{1cm} (32)
C Proof of Lemma 2

For any $n \in [N]$, we define the $dT \times dT$ block-diagonal matrix

$$M_n := \text{diag}(M_{1,n}, \ldots, M_{T,n}),$$

where the diagonal $d \times d$ diagonal block matrices are defined as follows:

$$M_{t,n} := n \left( \hat{\Sigma}_{t,n} - \Sigma_{t,n} \right) = n \sum_{s=1}^{n} x_{t,s} x_{t,s}^\top - \mathbb{E} \left[ x_{t,s} x_{t,s}^\top \bigg| \mathcal{F}_{s-1} \right].$$

(33)

We also set $M_0 = 0_{dT \times dT}$ a.s.

By construction $(M_n)_{n \geq 0}$ is a $\{\mathcal{F}_n\}_{n}$-martingale. It also admits a block-diagonal structure. Hence, in view of Assumption 1, we have for any $n \geq 1$

$$\|M_n - M_{n-1}\|_{\text{op}} \leq \max_{1 \leq t \leq T} \max_{x \in D_{t,n}} \|x\|_2^2 \leq b^2 d,$$ a.s.

(34)

(35)

Next, we consider the quadratic process:

$$\langle M \rangle_n = \sum_{s=1}^{n} \mathbb{E} \left[ (M_s - M_{s-1})^2 \bigg| \mathcal{F}_{s-1} \right] = \text{diag}(\langle M_{1,n} \rangle, \ldots, \langle M_{T,n} \rangle),$$

(36)

where for any $1 \leq t \leq T$,

$$\langle M_{t,n} \rangle = \sum_{s=1}^{n} \mathbb{E} \left[ \left( x_{t,s} x_{t,s}^\top - \mathbb{E} \left[ x_{t,s} x_{t,s}^\top \bigg| \mathcal{F}_{s-1} \right] \right)^2 \bigg| \mathcal{F}_{s-1} \right]$$

$$= \sum_{s=1}^{n} \mathbb{E} \left[ \|x_{t,s}\|_2^2 x_{t,s} x_{t,s}^\top \bigg| \mathcal{F}_{s-1} \right] - \left( \mathbb{E} \left[ x_{t,s} x_{t,s}^\top \bigg| \mathcal{F}_{s-1} \right] \right)^2 .$$

Taking the operator norm, we obtain by Cauchy-Schwartz’s inequality

$$\|\langle M \rangle_n\|_{\text{op}} \leq \max_{1 \leq t \leq T} \max_{u \in \mathbb{R}^d} \sum_{s=1}^{n} \mathbb{E} \left[ \|x_{t,s}\|^2 \langle x_{t,s}, u \rangle^2 \bigg| \mathcal{F}_{s-1} \right]$$

$$\leq b^2 d \max_{1 \leq t \leq T} \max_{u \in \mathbb{R}^d} \sum_{s=1}^{n} \mathbb{E} \left[ \langle x_{t,s}, u \rangle^2 \bigg| \mathcal{F}_{s-1} \right] .$$

(37)

Recall that at round $n$, $x_{t,n}$ can takes values in the set $D_{t,n} = \{\tilde{x}_{t,1}, \ldots, \tilde{x}_{t,K}\} \subset \mathbb{R}^d$ where, according to Assumption 1, the arms $\tilde{x}_{t,k}$ are drawn independently of $\mathcal{F}_{s-1}$ and admit zero mean and covariance $\Sigma_k$ respectively. This implies that, for any $t \in [T]$ and $s \in [n]$,

$$\mathbb{E} \left[ \langle x_{t,s}, u \rangle^2 \bigg| \mathcal{F}_{s-1} \right] \leq \max_{1 \leq k \leq K} \|\Sigma_k\|_{\text{op}},$$ a.s.

23
Combining the previous display with (37), we get that
\[
\|\langle M \rangle_n\|_{\text{op}} \leq b^2 d n \max_{1 \leq k \leq K} \|\Sigma_k\|_{\text{op}}, \quad a.s.
\] (38)

Then we can apply the Freedman inequality for matrix martingales (Theorem 1.2 in Oliveira (2010)). We get for all \(x > 0\), with probability at least \(1 - e^{-x}\)
\[
\|M_n\|_{\text{op}} \leq C \left( \sqrt{\max_{1 \leq k \leq K} \|\Sigma_k\|_{\text{op}}} \sqrt{\frac{b^2 d(x + \log(dT))}{n}} \sqrt{\frac{b^2 d(x + \log(dT))}{n}} \right),
\] (39)

for some absolute constant \(C > 0\).

### D Proof of Lemma 3

The proof follows by the next argument
\[
\left| \|\text{Vec}(\Delta)\|_{\Sigma_0}^2 - \|\text{Vec}(\Delta)\|_{\Sigma_1}^2 \right| \leq \|\Sigma_0 - \Sigma_1\|_{\text{op}} \|\text{Vec}(\Delta)\|_2^2 \leq \tilde{\lambda} \|\text{Vec}(\Delta)\|_2^2.
\]

According to Definition 1, let us assume \(\Delta\) to satisfy \(||\Pi(\Delta)||_1 \leq 3 \|\Delta - \Pi(\Delta)\|_1\), then the RSC condition gives
\[
\|\Delta\|_F = \|\text{Vec}(\Delta)\|_2 \leq \frac{\|\text{Vec}(\Delta)\|_{\Sigma_0}^2}{\kappa(\Sigma_0)}.
\]

Combining these two last results we have
\[
\left| \|\text{Vec}(\Delta)\|_{\Sigma_0}^2 - \|\text{Vec}(\Delta)\|_{\Sigma_1}^2 \right| \leq \tilde{\lambda} \frac{\|\text{Vec}(\Delta)\|_{\Sigma_0}^2}{\kappa(\Sigma_0)}.
\]

Equivalently, the following result holds
\[
\left| \frac{\|\text{Vec}(\Delta)\|_{\Sigma_1}^2}{\|\text{Vec}(\Delta)\|_{\Sigma_0}^2} - 1 \right| \leq \frac{\tilde{\lambda}}{\kappa(\Sigma_0)}.
\]

The statement follows directly by the selected \(\tilde{\lambda}\).

### E Proof of Theorem 1

We start by considering the instantaneous multi-task regret
\[
\tilde{R}_n = \sum_{t=1}^{T} R_{t,n} = \sum_{t=1}^{T} \langle x_{t,n}^*, w_t \rangle - \langle x_{t,n}, w_t \rangle \leq \sum_{t=1}^{T} \|x_{t,n}^* - x_{t,n}\|_\infty \|w_t\|_1 \leq 2LTb
\]

where \(x_{t,n}^* = \arg \max_{x \in \mathcal{D}_{t,n}} x^\top w_t\) and in the last inequality we relied on Assumption 1.

We will now split the regret into two phases. During the first \(N_0\) interactions the collected data will not meet the \(RI\) condition. Hence, the incurred regret will be of order \(2N_0LTb\).
Conversely, from the \( N_0 + 1 \)-th round up to the \( N \)-th one, the RSC condition will be met allowing the result of Lemma 1. Next we have

\[
\sum_{n=\lceil N/2 \rceil}^{N} R_{s} = \sum_{n=\lceil N/2 \rceil}^{N} \sum_{t=1}^{T} \langle x_{t,n}^*, w_t - \hat{w}_{t,n} \rangle + \sum_{n=\lceil N/2 \rceil}^{N} \sum_{t=1}^{T} \langle x_{t,n}^*, x_{t,n}, \hat{w}_{t,n} \rangle + \sum_{n=\lceil N/2 \rceil}^{N} \sum_{t=1}^{T} \langle x_{t,n}, \hat{w}_{t,n} - w_t \rangle
\]

\[
\leq \sum_{n=\lceil N/2 \rceil}^{N} \sum_{t=1}^{T} \langle x_{t,n}^*, w_t - \hat{w}_{t,n} \rangle + \sum_{n=\lceil N/2 \rceil}^{N} \sum_{t=1}^{T} \langle x_{t,n}, \hat{w}_{t,n} - w_t \rangle = \sum_{n=\lceil N/2 \rceil}^{N} \sum_{t=1}^{T} \langle x_{t,n}^* - x_{t,n}, w_t - \hat{w}_{t,n} \rangle
\]

(40)

where we have used that for any \( 1 \leq n \leq N \), \( \sum_{t=1}^{T} \langle x_{t,n}^* - x_{t,n}, \hat{w}_{t,n} \rangle \leq 0 \) a.s. by definition of our policy.

Next, Cauchy-Schwartz’s inequality gives

\[
\left| \sum_{t=1}^{T} \langle x_{t,n}^* - x_{t,n}, w_t - \hat{w}_{t,n} \rangle \right| \leq \| X_n^* - X_n \|_F \| \hat{W}_n - W \|_F ,
\]

(41)

where \( X_n \in \mathbb{R}^{d \times T} \) is the matrix of selected arms at time \( n \) for the \( T \) tasks.

By Assumption 1, \( \| X_n^* - X_n \|_F \leq b \sqrt{2dT} \). Recall that Lemmas 1, 4, 2 combined with Proposition 1 gives, for any \( \lceil N_0 \rceil \leq n \leq N \) and any \( \delta \in (0, 1) \), with probability at least \( 1 - \frac{\delta}{N} \),

\[
\left\| \hat{W}_{n+1} - W \right\|_F \lesssim_{n, \sigma, C_x, \kappa(\Sigma), \max_1 \leq k \leq K} \left\{ \| \Sigma_k \|_{op}^{1/2} \right\} \sqrt{\frac{T}{n}} \left( \sqrt{(T + d)} \sqrt{\log(2N\delta^{-1})} \right).
\]

Combining the previous display with (41), we obtain with probability at least \( 1 - \frac{\delta}{N} \)

\[
\left| \sum_{t=1}^{T} \langle x_{t,n}^* - x_{t,n}, w_t - \hat{w}_{t,n+1} \rangle \right| \leq b \sqrt{\frac{dT}{n}} \left( \sqrt{(T + d)} \sqrt{\log(2N\delta^{-1})} \right).
\]

(42)

Summing over \( n \) in the previous display along with an union bound argument and (40) gives with probability at least \( 1 - \delta \)

\[
\sum_{n=\lceil N_0 \rceil}^{N} R_s \leq C \sqrt{NdTr} \left( \sqrt{(T + d)} \sqrt{\log(2N\delta^{-1})} \right) ,
\]

(43)

where \( C = C \left( b, \eta, \sigma, C_x, \kappa(\Sigma), \max_1 \leq k \leq K \left\{ \| \Sigma_k \|_{op}^{1/2} \right\} \right) \) is a finite constant under our assumptions.

### F Proof of Theorem 2

We consider a specific deterministic instance where \( T = r \) and \( d = 2r \). In order to satisfy Assumption 3 we consider the task vectors to be \( r \) jointly sparse with \( s = r + 1 \) non-zero coefficients. Specifically, we assume the task matrix to be defined as

\[
W = \begin{bmatrix} 1_{r \times r} \\ I_r \end{bmatrix} \in \mathbb{R}^{d \times T}.
\]
The rank of the proposed matrix is equal to \( r \). We have assumed the \( d \)-dimensional unknown vector parameters \( \mathbf{w}_1, \ldots, \mathbf{w}_T \) to shared exactly the first \( r \) ones and be different in the remaining features. Now, without loss of generality we consider the case where we have \( K = r \) arms\(^1\). Moreover, we assume the contexts to be fixed and associated with one orthonormal basis \( \{ \mathbf{e}_1, \ldots, \mathbf{e}_K \} \in \mathbb{R}^T \). At start one arm \( \tilde{i} \in [r] \) is selected uniformly at random to be the \textit{good} one and will not change over tasks and rounds. Let us assume \( \tilde{i} = r \), its context vector will then be\(^2\)

\[
\mathbf{x}_r = \left( \frac{1}{2} + \frac{1}{4} \sqrt{\frac{Kd}{TN} - \epsilon} \right) \mathbf{e}_r^\top \in \mathbb{R}^{2r},
\]

where \( \epsilon > 0 \) is a small constant and we append vector \( \epsilon \mathbf{e}_r \) just to obtain a non-singular covariance matrix \( \Sigma \) (this is necessary to met the RSC condition Def. 1).

We consider all the other arms \( i \in \{0, \ldots, K\} \setminus \{\tilde{i}\} \) to be associated with contexts \( \mathbf{x}_i = \left[ \left( \frac{1}{2} - \epsilon \right) \mathbf{e}_i^\top \right] \in \mathbb{R}^{2r} \). Then, for any context and task, the RHS of the context vector at most contributes \( \epsilon \) to the reward. Hence, we can let \( \epsilon \) become arbitrarily small (but positive) and forget about the last \( r \) features. In the following proof we can proceed as if we are solving a single task which lasts for \( TN \) rounds, indeed all task vectors share the same first \( r \) features. We can now set the noise \( \eta \) such that all arms have expected reward \( \frac{1}{2} \) except for arm \( \tilde{i} \) which has expected reward \( \frac{1}{2} + \frac{1}{4} \sqrt{\frac{Kd}{TN}} \). For each task \( t \in [T] \), trial \( n \in [N] \), the expected reward of any algorithm will then be

\[
\mathbb{E}_T[Y_{t,n}] = \frac{1}{2} + \frac{1}{4} \sqrt{\frac{Kd}{TN}} \mathbb{P}_T[I_{t,n} = \tilde{i}],
\]

where random variable \( I_{t,n} \in \mathcal{D}_{t,n} \) denotes the arm picked by the algorithm when facing task \( t \) at round \( n \). We also used \( \mathbb{E}_T[\cdot] \) (\( \mathbb{P}_T[\cdot] \)) to denote the expected value (probability) associated to the true random assignment of rewards conditioned on the fact that arm \( \tilde{i} \) is the good arm. Hence, considering any algorithm, its expected gain \( G(T, N) = \sum_{t=1}^{T} \sum_{n=1}^{N} Y_{t,n} \) (sum of rewards) satisfies

\[
\mathbb{E}_T[G(T, N)] = \frac{TN}{2} + \frac{1}{4} \sqrt{\frac{Kd}{TN}} \mathbb{E}_T[N_{\tilde{i}}], \tag{44}
\]

where \( N_{\tilde{i}} \) represents the number of times the algorithm has selected arm \( \tilde{i} \) overall the \( TN \) rounds. Now, applying (Auer et al., 2002, Lemma A.1) to \( N_{\tilde{i}} \in [0, TN] \) we obtain

\[
\mathbb{E}_T[N_{\tilde{i}}] \leq \mathbb{E}_{\text{unif}}[N_{\tilde{i}}] + \frac{TN}{2} \sqrt{-\mathbb{E}_{\text{unif}}[N_{\tilde{i}}] \log \left( 1 - \frac{Kd}{4TN} \right)}
\]

where \( \mathbb{E}_{\text{unif}} \) represents the expected value with respect to a uniformly random choice of all arms rewards. Summing over the arms we get

\[
\sum_{i=1}^{K} \mathbb{E}_T[N_i] \leq TN + \frac{TN}{2} \sqrt{-TNK \log \left( 1 - \frac{Kd}{4TN} \right)}.
\]

Combining this result with the one of Equation 44 gives

\[
\mathbb{E}_n[G(T, N)] = \frac{1}{K} \sum_{i=1}^{K} \mathbb{E}_T[G(T, N)] \leq \frac{TN}{2} + \frac{1}{4} \left( \sqrt{\frac{TN}{Kd}} + \frac{TN}{2} \sqrt{-\log \left( 1 - \frac{Kd}{4TN} \right)} \right),
\]

\(^1\)The same proof would hold if \( K \geq r \).
where we used $\mathbb{E}_*[:]$ to represent the arm expected values computed with the adopted random assignment. Finally, we have that the expected gain of the best arm is at least equal to the one of the good one, hence

$$
\mathbb{E}_*[G^*(T,N)] = \frac{TN}{2} + \frac{1}{4} \sqrt{\frac{Kd}{TN}} TN.
$$

By combining the two last obtained results and recalling that we chose $K = r$, we conclude that

$$
\mathbb{E}_*[G^*(T,N) - G(T,N)] \geq \Omega(\sqrt{TNdr}) .
$$

### G Proof of Remark 2

Similarly to what we have done in Section 5 we consider a specific deterministic instance with $d = 2s$, where $s$ is the sparsity index. We then fix the regression vector parameter to be defined as

$$
w = [1_s^\top | 0_s^\top] \in \mathbb{R}^d .
$$

From now one, without loss of generality we consider the case where we have $K = s$ arms\footnote{The same proof would hold if $K \geq s$.}. We assume also the contexts to be fixed and associated with one orthonormal basis $\{e_1, \ldots, e_K\} \in \mathbb{R}^s$. As in the proof of Theorem 2, before starting one arm $i \in [s]$ is selected uniformly at random to be the good one and will not change over the $N$ rounds. Let us assume $i = s$, its context vector will then be

$$
x_i = \left[ \left( \frac{1}{2} + \frac{1}{4} \sqrt{\frac{K}{N}} \right) e_i^\top \right] \in \mathbb{R}^d ,
$$

where $\epsilon > 0$ is a small constant and we append vector $\epsilon e_i$ just to obtain a non-singular covariance matrix $\Sigma$ (this is necessary to meet the RE conditions). We consider all the other arms $i \in \{0, \ldots, K\} \setminus \{i\}$ to be associated with contexts $x_i = [\left( \frac{1}{2} \right) e_i^\top | \epsilon e_i^\top] \in \mathbb{R}^d$. Slightly differently from what we have done for Theorem 2, here we do not need the $\epsilon$ contribute in the first $s$ features. Indeed, given the chosen $w$ vector, $\epsilon$ will never contribute in the reward definition. We can now set the noise $\eta$ such that all arms have expected reward $\frac{1}{2}$ except for arm $\bar{i}$ which has expected reward $\frac{1}{2} + \frac{1}{4} \sqrt{\frac{K}{N}}$. For each trial $n \in [N]$, the expected reward of any algorithm will then be

$$
\mathbb{E}_i[Y_n] = \frac{1}{2} + \frac{1}{4} \sqrt{\frac{K}{N}} \mathbb{P}_i[I_i,n = \bar{i}] ,
$$

where random variable $I_i \in \mathcal{D}_n$ denotes the arm picked by the algorithm when facing the $n$-th round. Now, considering any algorithm, its expected gain $G(N) = \sum_{n=1}^N Y_n$ (sum of rewards) satisfies

$$
\mathbb{E}_i[G(N)] = \frac{N}{2} + \frac{1}{4} \sqrt{\frac{K}{N}} \mathbb{E}_i[N_\bar{i}] ,
$$

where $N_\bar{i}$ represents the number of times the algorithm has selected arm $\bar{i}$ overall the $N$ rounds. The rest of proof consists in the combination of (Auer et al., 2002, Lemma A.1) with the exact same steps applied for Theorem 2.
## Experiments Details

In Table 1 we provide the average cumulative rewards and the standard deviations associated to Figures 1 and 2 presented in the main body of the paper.
