Bettors’ reaction to match dynamics — Evidence from in-game betting

Rouven Michels*,† Marius Ötting† Roland Langrock†

Abstract

It is still largely unclear to what extent bettors update their prior assumptions about the strength or form of competing teams considering the dynamics during the match. This is of interest not only from the psychological perspective, but also as the pricing of live odds ideally should be driven both by the (objective) outcome probabilities and also the bettors’ behaviour. Analysing large and high-resolution data from live betting in German football, we find that stakes in the live-betting market are driven both by perceived pre-game strength and by in-game strength as implied by measurable events such as shots and passes. Both effects vary over the course of the match.

Keywords— OR in sports, live betting, state-space model, stochastic volatility, time series analysis

1 Introduction

Given the economic relevance of betting markets — the gross gaming revenue was reported as 41.7 billion Euro in 2020 in Europe [European Gaming & Betting Association 2020] — it is of much interest to understand the behaviour of the market’s participants, i.e. the bettors. From the bookmakers’ perspective, it is first of all crucial to avoid inefficiencies in the pricing of odds. Furthermore, for profit maximisation it may be beneficial to exploit particular patterns in bettors’ actions, such as a favourite-longshot bias (or the reverse bias). Such patterns and

*corresponding author: r.michels@uni-bielefeld.de
†Bielefeld University, Universitätsstraße 25, 33615 Bielefeld, Germany
potential biases are also interesting from the psychological perspective, and several studies have indeed already focused on betting behaviour, e.g. investigating the ‘gambler’s fallacy’ (Tversky and Kahneman, 1974; Clotfelter and Cook, 1993), the reaction to a perceived ‘hot hand’ (Sundali and Croson, 2006; Paul et al., 2014), but also the drivers of demand for sports bets more generally (Humphreys et al., 2013; Deutscher et al., 2019).

Sports betting takes place both in the pre-game (bets placed before kick-off) and in the in-game (bets placed during games) market. Although only 45% of the betting volume in Europe (European Gaming & Betting Association, 2020) is placed in the pre-game market, empirical research to date has largely focused on this market, investigating market (in-)efficiencies, over- and underreaction of bettors, drivers of betting volume and forecasting of match outcomes, to name but a few (see, e.g. Thaler and Ziemba, 1988; Vergin, 2001; Dixon and Pope, 2004; Feddersen et al., 2017; Deutscher et al., 2018; Brown and Reade, 2019; Butler et al., 2021; Durand et al., 2021). In contrast, for the in-game market, the existing literature to date has mostly focused on inefficiencies (see, e.g. Debnath et al., 2003; Choi and Hui, 2014; Croxson and Reade, 2014), such that in particular the betting behaviour in this important and highly dynamic market is not yet well understood. The principle question motivating this contribution thus is the following: What are the drivers of bet placements in the in-game market? And in particular: To what extent are these related to match dynamics?

For the pre-game betting market, building a forecast based on information such as the (perceived) teams’ strength is comparable, conceptually, to a fundamental analysis in the financial market (Abarbanell and Bushee, 1997). In the latter, the incentive to buy stocks — the counterpart of a sports bet placement — is that people feel confident that the ‘true’ value of a company is larger than the actual stock price. Market analysts estimate the former by means of, e.g. the debt-equity-ratio and the earnings before interest, taxes, depreciation, and amortisation (EBITDA; Mukherji et al., 1997; Quirin et al., 2000; Baresa et al., 2013). Thus, investments based on a fundamental analysis correspond to an expectation of net profits in the long run. In contrast, exploiting short-time fluctuations in the financial market can be attempted based on a technical analysis (see, e.g. Edwards et al., 2018; Brown and Jennings, 1989). In that case, the investor examines several quantitative indicators such as moving averages to build a short-term forecast (Zhu and Zhou, 2009). While we do not want to stretch the analogy too much, we argue that in-game bettors can, in principle, follow not only a strategy similar to a fundamental analysis, essentially considering the current score relative to fixed variables such as the team strength, but also a strategy more similar to a technical analysis, incorporating information from short-term measures related for example
to ball possession, tackles, goal-scoring opportunities or passes completed. To what extent either of these two strategy types drives the placement of bets in the in-game market is the focus of this work.

We investigate the effects of both fixed team information and in-game dynamics on the stakes placed in the in-game market based on two large and high-resolution data sets from the 2017/18 season of the German Bundesliga. The first data set, provided by a large European bookmaker, covers detailed betting data, specifically in-game betting odds and volumes for all 306 matches played in the 2017/18 season. The second data set, provided by Pappalardo et al. (2019), comprises WyScout event data, consisting of information on events such as shots on goal, passes, 1-on-1 situations and set pieces, for all 306 matches. The combination of these two large data sets enables us to investigate in particular the potential effects of in-game dynamics on betting behaviour, and how these may vary over the course of a match — the expectation being that the importance of in-game (pre-game) information will increase (decrease) over time.

2 Data

We use in-game stakes placed during all 306 matches of the 2017/2018 German Bundesliga season to investigate the investment behaviour of bettors during football matches. In particular, the corresponding data considered cover bets on the match outcome, i.e. home win or away win (we exclude bets on a draw from our analysis). These data, which we were provided to us by one of the largest bookmakers in Europe (with most of its customers located in Germany), have a 1 Hz resolution. This temporal resolution is finer than necessary with respect to our research objective, such that to simplify the modelling we aggregate the second-by-second stakes into intervals of one minute. To compare stakes across teams and matches, we calculate relative stake per team, where for each interval we divide the amount of stakes placed on each team by the total amount placed on either team. The two teams’ relative stakes thus always sum to 1, such that it is sufficient to analyse the relative stakes from the point of view of one team only. Therefore, without loss of generality, in the following we will consider the relative stakes placed on the home team only. The processed data set then comprises $N = 306$ time series, $\{y_{n,t}\}, n = 1, \ldots, 306, \text{ with } t, t = 1, \ldots, T$, indicating the minute of the match. Towards the end of the injury time, much less stakes are placed, such that we truncate all time series at minute $t = 85$ to avoid the need to deal with the much increased variation. Overall, 26 010 observations of relative stakes are considered.
To investigate the drivers of betting behaviour, as represented here by the relative stakes being placed, we consider both static (pre-game) as well as dynamic (in-game) covariate information. For the former, we use the Elo rating (downloaded from [http://clubelo.com/](http://clubelo.com/)) as a proxy for the pre-game strength of a team ([Hvattum and Arntzen, 2010](https://www.journals.uchicago.edu/doi/abs/10.1086/665579) [Angelini et al., 2022](https://doi.org/10.1016/j.jebo.2021.10.002)). The Elo rating remains constant within matches but varies across matches, according to the current form of a team. To account for both teams’ strength, we consider the difference of their Elo ratings (elodiff).

To additionally investigate the effect of in-game actions on the stakes placed, an additional comprehensive data set on in-game match events is considered. These data, again collected at 1 Hz, were provided by the company WyScout and were made publicly available by [Pappalardo et al., 2019](https://www.mdpi.com/2072-4292/12/3/917). They contain information on all relevant actions during the match, together with a time stamp as well as the associated location on the pitch, indicated by $x$– and $y$–
coordinates. From the WyScout in-game data, we extract covariate information related to the match action, aiming to measure how the in-game team strength evolves dynamically throughout the match. To this end, several simple summary statistics could be used, e.g. the number of shots, the number of passes or the average distance of actions to the opposing goal. However, such simple metrics have been shown to be relatively poor predictors for the match outcome in football (Mackenzie and Cushion 2012, Carling et al. 2014).

To capture the in-game strength of a team appropriately we thus consider a more refined metric for measuring the value of actions on the pitch, namely the so-called Valuing Actions by Estimating Probabilities (VAEP) approach (Decroos et al. 2019).

The idea of the VAEP is to measure the value of any action, e.g. a pass or a tackle, with respect to both the probability of scoring and the probability of conceding a goal. For illustration, Figure 1 shows an example sequence of actions and their associated VAEP values, obtained using predictive machine learning methods, in particular gradient-boosted trees — see the Appendix for more details. From the action-level VAEP values, we build the covariate vaepdiff, where we consider the differences between the teams’ VAEP values aggregated over 1-minute intervals. The higher the value of vaepdiff, the more the momentum of the match is with the team for which the relative stakes are modelled. Figure 2 shows an example of how vaepdiff evolves over time along with our response variable, the relative stakes. Table 1 displays summary statistics on the VAEP and on all remaining variables considered in our analysis.

3 Modelling relative stakes

The time series of relative stakes exhibit strong positive serial correlation (cf. Figure 2). This correlation does not result from a potential direct effect of the stakes placed in any given minute on the stakes placed in subsequent one-minute intervals, as individual bettors (for
the most part) act independently of each other. Instead, the correlation is induced by the market progressing through different phases, corresponding for example to extended periods of time with bets placed predominantly on the home team (cf. minutes 25–65 in Figure 2). Such different phases can be formalised as a latent variable within a state-space model (SSM), which therefore constitutes the natural modelling approach for our data: stakes are driven by the current underlying market phase (e.g. leaning towards bets being placed on the home team), and the unobserved market phase evolves probabilistically over time, exhibiting serial correlation and hence inducing serial correlation also in the observed time series of stakes.

More specifically, such an SSM comprises two processes, (i) an unobserved, serially correlated state process \( \{ g_{n,t} \} \), in our application to be seen as an indicator of the market phase, with higher values implying a stronger bias towards bet placement on the home team, and (ii) an observed state-dependent process \( \{ y_{n,t} \} \), which is driven by \( \{ g_{n,t} \} \) and in our case is
the time series of relative stakes placed. For simplicity, the subscript \( n \), indicating the match considered, is omitted in the following. The state variables are assumed to be first-order Markovian, i.e.

\[
f(g_{t+1}|g_1, \ldots, g_{t-1}) = f(g_{t+1}|g_t),
\]

and the observations are assumed to be conditionally independent of each other and of previous states, given the current state:

\[
f(y_t|g_1, \ldots, g_t, y_1, \ldots, y_{t-1}) = f(y_t|g_t).
\]

In the next section, we develop the specific model formulation, i.e. the precise form of the conditional distributions \( f(g_{t+1}|g_t) \) and \( f(y_t|g_t) \), used to model the time series of relative stakes. Details on the implementation of the maximum likelihood estimation of the model parameters are provided in the Appendix.

### 3.1 Baseline state-space model

Our response variable \( y_t \), the relative amount of stakes placed on the home team, is continuous-valued with support \([0,1]\), rendering the beta distribution a natural choice for modelling purposes. However, the support of the regular beta distribution is \((0,1)\), such that we use the beta-inflated distribution (BEINF) to account for the fact that in some intervals stakes are placed on one team only (in which case \( y_t = 0 \) or \( y_t = 1 \)). We follow the parametrisation proposed by Rigby et al. (2019), such that

\[
y_t \sim \text{BEINF}(\mu_t, \sigma, p, q), \quad \text{with} \quad f(y_t) = \begin{cases} 
  p, & \text{if } y_t = 0; \\
  (1 - p - q)h(y_t), & \text{if } 0 < y_t < 1; \\
  q, & \text{if } y_t = 1,
\end{cases}
\]

for \( 0 \leq y_t \leq 1 \). Here \( h(y_t) \) is the density function of the regular beta distribution, i.e.

\[
h(y_t, a, b) = \frac{y_t^{a-1}(1 - y_t)^{b-1}}{B(a, b)},
\]

with the beta function \( B(a, b) \). The shape parameters \( a \) and \( b \) are not directly amenable to regression modelling, such that we consider a reparametrisation in terms of the beta distribution’s mean \( \mu_t \) and its standard deviation \( \sigma \) (Rigby et al. 2019). From \( \mu_t \) and \( \sigma \) the associated shape parameters are obtained as \( a = \mu_t(1 - \sigma^2)/\sigma^2 \) and \( b = (1 - \mu_t)(1 - \sigma^2)/\sigma^2 \). Assuming
BEINF-distributed relative stakes, Figure 3 displays the exact dependence structure of our SSM as a directed acyclic graph. Specifically, to account for the dynamic nature of the relative stakes within matches, the mean $\mu_t$ is assumed to be time-varying and is modelled as follows:

$$\mu_t = \logit^{-1}(\alpha_0 + g_t + elodiff).$$  \hspace{1cm} (1)

The rationale of the three components of the linear predictor is as follows. First, since we consider the relative stakes placed on the home team, the intercept $\alpha_0$ is included to capture potential biases in stake placement caused by the home advantage (see, e.g. Edwards and Archambault, 1979; Goller and Krumer, 2020). Second, information on the current market phase is included via $g_t$, thereby accounting for phases with stronger biases in bet placement on either team. Third, we include the difference between both teams’ Elo ratings ($elodiff$) to address systematic effects such as potential favourite-longshot biases, or their reverse, throughout matches (see, e.g. Cain et al., 2000, Cain et al., 2003).

The unobserved variable corresponding to the market phase, $g_t$, is modelled as an autoregressive process of order 1, with additional covariate dependence:

$$g_t = \phi g_{t-1} + \beta vaepdiff_{t-1} + \omega \eta_t,$$  \hspace{1cm} (2)

with $\eta_t \sim \mathcal{N}(0, 1)$, $\omega > 0$ and $\phi \in (-1, 1)$. The in-game covariate $vaepdiff$ is included in the state variable $g_t$, as it seems natural to assume that potential effects of positive actions by a team will not necessarily be instantaneous — i.e. affecting the mean of the relative stakes only in the very minute the action took place — but rather accumulate and persist over some time. For example, from the bettor’s perspective, a single one-minute interval with high $vaepdiff$ values is not as likely to affect his or her betting decision as a positive spell of say 15 minutes of the team considered, with overall elevated $vaepdiff$ values. This is accounted for by allowing positive contributions of $vaepdiff$ to accumulate in $g_t$, which for $\phi > 0$ is persistent and hence to some extent memorises these contributions.

### 3.2 Varying coefficient state-space model

Due to the dynamic nature of football matches, it may very well be the case that the effects of $elodiff$ and $vaepdiff$ vary over time. Specifically, it seems intuitively plausible that the strength of the team, as measured by the Elo rating, is a strong predictor for betting activity at the beginning of a match when little additional information is available. Vice versa, towards
Figure 3: Dependence structure of the SSM used to model the relative stakes $y_t$, driven by the state variable $g_t$ corresponding to the market phase. Additional covariate dependence is assumed in both state-dependent and state process, for the former considering static (constant within matches) covariate information, for the latter considering dynamic covariate information built from event data.

the end of a match the teams’ performances during the match might become increasingly important for understanding betting dynamics. To allow the effects of $elodiff$ and $vaepdiff$ to vary over time, we replace $\alpha$ and $\beta$ in Eqs. (1) and (2) by time-varying parameters $\alpha_t$ and $\beta_t$, respectively. To avoid a priori assumptions on the functional forms of $\alpha_t$ and $\beta_t$, we model these functions nonparametrically using B-splines.

Since the seminal paper by Eilers and Marx (1996), the class of B-splines has rapidly gained popularity in nonparametric statistical modelling, and in recent years, B-spline-based modelling of functional effects has been embedded also in various types of SSMs (see, e.g. de Souza and Heckman 2014; Hambuckers et al. 2018; Mews et al. 2022). In our setting, $\alpha_t$ and $\beta_t$, the time-varying effects of $elodiff$ (on the mean relative stakes) and $vaepdiff$ (on the state variable indicating the market phase), are modelled as linear combinations of a finite
number of section-wise defined basis functions,

$$\alpha_t = \sum_{k=1}^{K} \nu_k^\alpha B_k(t), \quad \beta_t = \sum_{k=1}^{K} \nu_k^\beta B_k(t),$$  \hspace{1cm} (3)

for \( t = 1, \ldots, 85 \), where \( B_1, \ldots, B_K, \ k = 1, \ldots, K \), are fixed, equidistant B-spline basis functions of order three. We use cubic polynomial B-splines to obtain a twice continuously differentiable function, thus leading to smooth density estimates \cite{Langrock2017}. To prevent overfitting we add a roughness penalty term, thus considering so-called penalised B-splines, i.e. P-splines \cite{Eilers1996}. Specifically, we penalise high values of the second-order differences of adjacent coefficients in the linear combinations above. The sum of these second-order differences corresponds to an approximation of the integrated squared curvature of the functional estimate. The resulting penalised log-likelihood function is then given as follows (cf. \cite{Langrock2017}):

$$\ell_p = \log(L_{\text{approx}}) - \frac{\lambda_\alpha}{2} \sum_{k=3}^{K} (\Delta^2 \nu_k^\alpha)^2 - \frac{\lambda_\beta}{2} \sum_{k=3}^{K} (\Delta^2 \nu_k^\beta)^2,$$  \hspace{1cm} (4)

with the unpenalized likelihood function \( L_{\text{approx}} \) (see Eq. (6) in the Appendix), the second-order differences \( \Delta^2 \nu_k = \nu_k - 2 \nu_{k-1} + \nu_{k-2} \), and smoothing parameters \( \lambda_\alpha \) and \( \lambda_\beta \) to control the bias-variance trade-off. For \( \lambda_\alpha, \lambda_\beta \to \infty \) the varying coefficients \( \alpha_t \) and \( \beta_t \) simplify to a linear effect \cite{Eilers1996}. In other words, this nonparametric approach can capture complex time-varying effects if necessary and otherwise will typically collapse to simple linear modelling due to the penalisation of non-zero curvature.

Following \cite{Fahrmeir2013}, the tuning parameters \( \lambda_\alpha \) and \( \lambda_\beta \) are chosen via the Akaike Information Criterion (AIC), \( \text{AIC} = -2 \cdot l + 2 \cdot \hat{df} \), where \( l \) is the unpenalised likelihood under the fitted model and \( \hat{df} \) is an estimate of the degrees of freedom. The latter is obtained as the trace of the product of the Fisher information matrix for the unpenalized likelihood and the inverse Fisher information matrix for the penalized likelihood \cite{Gray1992}. Based on preliminary analyses we consider the following two-dimensional grid from which the smoothing parameters are chosen:

$$\Lambda_\alpha \times \Lambda_\beta = \{10, 500, 1000, 2500, 5000\} \times \{10, 25, 50, 100, 250\}.$$  \hspace{1cm} (5)

For each combination of \( \lambda_\alpha \in \Lambda_\alpha \) and \( \lambda_\beta \in \Lambda_\beta \), the model is fitted and the AIC calculated, then selecting the combination of \( \lambda_\alpha \) and \( \lambda_\beta \) that yields the lowest AIC value. A more detailed
discussion of the implementation of P-splines can be found in Langrock et al. (2017).

4 Results

4.1 Baseline state-space model

For the baseline SSM specified by (1) and (2), with the effects of $elodiff$ and $vaepdiff$ assumed to be constant over time, the parameter estimates are given in Table 2. The persistence in the state process was estimated to be fairly strong ($\hat{\phi} = 0.968$), corresponding to a positive correlation in the proportional allocation of stakes. In other words, if bets are placed predominantly on either of the two teams, this pattern tends to persist for some time. The effects of $elodiff$ and $vaepdiff$ were both estimated to be positive, confirming the intuition that team strength, both prior to the match and as manifested during the match itself, is valued by bettors. According to the AIC, this model is preferred over the model excluding $elodiff$ ($\Delta AIC = 339.17$) as well as over the model excluding $vaepdiff$ ($\Delta AIC = 529.59$). This is corroborated also by the 95% confidence intervals given in Table 2. Finally, we see confirmed that there is a systematic bias towards bets on home teams ($\hat{\alpha}_0 > 0$). In particular, if $g_t = elodiff = vaepdiff = 0$, then $\logit^{-1}(0.141) = 0.535 = 53\%$ of the bets are placed on the home team.

4.2 Varying coefficient state-space model

The varying coefficient SSM, which allows the effects of $elodiff$ and $vaepdiff$ to change as the match progresses, was estimated using $K = 10$ basis functions to build the functional effects according to (3). The model was fitted for all combinations of tuning parameters from $\Lambda_\alpha \times \Lambda_\beta$ as specified in (5), with the optimal choice being $(\lambda_\alpha, \lambda_\beta) = (5000, 10)$ according
Figure 4: Time varying P-Spline effects of the Elo variable ($\lambda_\alpha = 10$) as well as the VAEP variable ($\lambda_\beta = 5000$). The white area indicates the intervals data was considered for. The grey area indicates where outer knots are set.

According to the AIC, the model including time-varying effects of $\text{elodiff}$ and $\text{vaepdiff}$ is clearly favoured over the simpler model reported in Section 4.1 ($\Delta \text{AIC} = 186.02$).

Regarding the estimated parametric effects, the results again confirm serial correlation in
the state process ($\hat{\phi} = 0.971$) as well as a home team effect ($\hat{\alpha}_0 = 0.538$). The nonparametrically estimated time-varying effects of elodiff and vaepdiff are shown in Figure 4. The effect of elodiff on stake placement is estimated to be positive throughout the match, but with the effect size decreasing as the match progresses. This matches the intuition that the effect of elodiff — a variable measuring the overall strength of a team but not taking into account the actions on the pitch — should be largest when new information is limited, i.e. at the very beginning of matches. The associated smoothing parameter was selected to be very large ($\lambda_\alpha = 5000$), such that the estimated effect of elodiff does in fact decrease approximately linearly over time (even larger values of $\lambda_\alpha$ yield virtually identical results). In contrast, for vaepdiff we find a highly non-linear functional form of the effect size over time. The effect of vaepdiff — a variable measuring the in-game strength of a team — is estimated to slightly increase throughout the first half of a match, followed by a much more rapid increase in the second half. Bettors thus do value actions on the pitch, with positive spells of a team leading to a shift in the market’s momentum and eventually an increase in the relative stakes placed on that team. Perhaps most interestingly, the importance of in-game actions as drivers of betting volumes very rapidly increases towards the end of matches.

The results show that bettors incorporate information both on the perceived (pre-game) team quality as well as in-game dynamics when devising their betting strategy. This is in accordance with evidence found for financial markets, where more than 85% of investors rely on both fundamental as well as technical analysis (Lui and Mole, 1998), thus incorporating both the valuation of a company as well as the stock’s more short-term momentum.

5 Discussion

The estimated effect of in-game actions on stake placement indicates that bettors try to exploit the information provided by in-game dynamics. In contrast, for the example match Hamburger SV vs. Werder Bremen, Figure 5 illustrates that the betting odds and hence the implied winning probabilities appear to be unaffected by in-game actions as proxied by the VAEP differences. If bookmakers do not incorporate such information in their calculation of betting odds, this could lead to inefficiencies that could potentially be exploited by bettors. Merz et al. (2021) do indeed report that bookmakers do not adequately incorporate comprehensive performance information from previous matches when deriving odds, instead relying too heavily on the pure outcome and not factoring in the element of chance (e.g. that a team might have lost despite playing well).
Figure 5: Time series of the win probabilities of Hamburger SV for one example match from the data set (Hamburger SV vs. Werder Bremen). The vertical bars denote the differences between both teams’ VAEP values from the point of view of Hamburger SV. Despite urge phases seem to alternate, especially towards the end of the match between minutes 60 and 80, the corresponding win probability — derived by the in-game odds — does not fluctuate accordingly. The changes, respectively the steady decline, in the win probability are almost exclusively caused by the effect of the remaining time.

From a bookmaker’s point of view, it may thus be important to adapt their outcome probability models to better accommodate in-game event data. Corresponding models have been developed for various sports, including American Football [Lock and Nettleton 2014], cricket [Asif and McHale 2016], and rugby [Guan et al. 2020]. For football, Robberechts et al. (2019) used event data, in particular on passes and 1-on-1 situations, to derive a win probability model at a 1 Hz resolution. The resulting model-derived win probabilities exhibited much more fluctuations than those implied by our data on odds (Figure 5). Using dynamic control theory, Lorig et al. (2021) developed a framework for maximising bookmaker revenue by taking into account in-game information.

A possible psychological effect to be taken into account is that bettors might in fact overreact to in-game dynamics, with positive actions by a team leading them to overestimate the winning probabilities. This kind of overreaction to positive events has in fact already been reported in sports betting [Durand et al. 2021, Otting et al. 2021] and is also known
to occur in financial markets (see, e.g. Ma et al. 2005; Piccoli et al. 2017). In particular, Huang et al. (2007) showed that price-earning ratios in the financial market clearly deviate from expectations based on fundamentals, in other words that stock prices can be subject to an overreaction. In the in-game betting market, the estimated effect of the in-game dynamics might indicate a similar momentum-induced deviation from expectations based on pre-game strength (as the analogue to a company’s fundamentals).

In more general terms, while our study focused on a specific aspect of live betting — namely to what extent in-game dynamics affect bettor behaviour — it also illustrates the immense potential of sports data, the availability of which has improved thanks to data providers such as WyScout or StatsBomb. The analysis of such complex data requires sophisticated statistical modelling, and SSMs as applied in the present paper constitute a versatile framework to accommodate the time series nature of most sports data (cf. Koopmeiners 2012; Green and Zwiebel 2018; Œtting et al. 2020; Mews and Œtting 2022). We thus anticipate an uptake of this type of modern statistical modelling tools for further research, in particular into the dynamics of live betting markets, but also in other sports settings.

A.1 Computation of the VAEP values

The VAEP values are obtained using predictive machine learning as proposed in Decroos et al. (2019), fitting gradient-boosted trees to the data on in-game actions across five different seasons as well as one World Cup and one European Championship (data provided by Papalardo et al., 2019). We obtain positive but small values for successful passes and dribblings in midfield, whereas corresponding actions yield larger VAEP values when occurring closer to the goal. Since a saved shot is hardly ever followed by a goal, and the VAEP value is defined as the difference between the probability of scoring a goal before and after an action, the VAEP value of a shot is most often negative. However, it can be assumed that bettors regard (saved) shots as a positive rather than a negative action, and therefore we omit all shots on goal. This includes actual goals, as we are interested in quantifying only those events that do not directly change the outcome of the game. Major news such as goals do of course also influence betting behaviour (Ötting et al., 2021).

A.2 Calculating and optimising the SSM likelihood

The likelihood of our non-linear and non-Gaussian SSM involves multiple integrals, which we evaluate numerically by finely discretising the state process as first suggested by Kitagawa (1987). This discretisation corresponds to a reformulation of the SSM as a hidden Markov model (HMM) with a large state space (Zucchini et al., 2016). This reformulation allows us to apply recursive techniques from the HMM toolbox, in particular for calculating the approximate likelihood (for a single match) as

$$L_\text{approx} = \delta \mathbf{P}(y_1) \Gamma(1) \mathbf{P}(y_2) \Gamma(2) \mathbf{P}(y_3) \ldots \Gamma(T-2) \mathbf{P}(y_{T-1}) \Gamma(T-1) \mathbf{P}(y_T) \mathbf{1},$$  \hspace{1cm} (6)

with $\mathbf{1} = (1, \ldots, 1) \in \mathbb{R}^m$, $\delta$ and $\Gamma(t)$, $t = 1, \ldots, T - 1$, denoting the initial state distribution and the transition probability matrix, respectively, of the approximating HMM, and the diagonal matrices $\mathbf{P}(y_t)$, $t = 1, \ldots, T$, comprising the state-dependent densities of the relative stakes at time $t$ (cf. Zucchini et al., 2016, Chapter 11, for more details). To evaluate the likelihood for the complete data set, independence of stakes placed across matches is assumed, such that the joint likelihood for all 306 matches is simply the product of the likelihoods of the individual matches. Parameter estimation is then carried out numerically by optimising
the likelihood — or, in case of the varying coefficient model, the penalised likelihood — using a Newton-Raphson-type scheme.
