ABSTRACT

Model selection (MS) and model averaging (MA) are two popular approaches when having many candidate models. Theoretically, the estimation risk of an oracle MA is not larger than that of an oracle MS because the former one is more flexible, but a foundational issue is: does MA offer a substantial improvement over MS? Recently, a seminal work: [Peng and Yang (2021)], has answered this question under nested models with linear orthonormal series expansion. In the current paper, we further reply this question under linear nested regression models. Especially, a more general nested framework, heteroscedastic and autocorrelated random errors, and sparse coefficients are allowed in the current paper, which is more common in practice. In addition, we further compare MAs with different weight sets. Simulation studies support the theoretical findings in a variety of settings.

Some key words: Asymptotic efficiency, model averaging, model selection, risk comparison, weight set.

1 Introduction

In the past two decades, model selection (MS) has received growing attention in statistics and econometrics. When a list of candidate models is considered, MS attempts to select a single best model. A large number of MS criteria have been proposed in the literature, including Akaike information criterion (AIC; [Akaike 1973]), Mallows’ $C_p$ ([Mallows 1973]), Bayesian information criterion (BIC; [Schwarz 1978]), cross-validation (CV; [Allen 1974, Stone 1974]), and so on. Model averaging (MA) is an alternative to MS by taking a weighted average of the estimators/predictions from candidate models, and thus is a smoothed extension of MS, and can potentially reduce risk relative to MS ([Magnus et al. 2010, Yuan and Yang 2005]).

Asymptotic efficiency (or asymptotic optimality) is a key theoretical goal pursued in both
MS and MA literature. It states that the risk (or loss) of MS (or MA) is equivalent to that of
the infeasible oracle candidate model (or averaging estimator/prediction). For MS methods,
AIC is asymptotic efficient but BIC is not in the nonparametric framework \( \text{Shao, 1997; Shibata, 1983; Li, 1987} \) established the asymptotic efficiency of \( C_p \) and leave-one-out CV (LOO-CV) for the homoscedastic nonparametric regression; \( \text{Andrews, 1991} \) extended the
results of \( \text{Li, 1987} \) to the case of heteroscedastic errors. See \( \text{Ding et al., 2018} \) for a recent
review on the properties of MS methods.

For asymptotic optimality of MA, \( \text{Hansen, 2007} \) established the asymptotic optimality
for Mallows Model Averaging (MMA) when the candidate models are nested and the weights
are restricted to a discrete set. \( \text{Wan et al., 2010; Zhang, 2021} \) extended the result of
\( \text{Hansen, 2007} \) to a non-nested model setting with continuous weights. \( \text{Hansen and Racine, 2012} \) established the asymptotic optimality of Jackknife Model Averaging (JMA) for heteroscedastic errors with the weight contained in a discrete set. \( \text{Zhang et al., 2013} \) broadened
\( \text{Hansen and Racine, 2012} \)’s scope of analysis to dependent data and a continuous weight set.
\( \text{Liu and Okui, 2013} \) proposed a heteroscedasticity-robust model averaging with asymptotic
optimality. \( \text{Ando and Li, 2014, 2017} \) removed the conventional restriction that the sum
of weights equals one in MA and established the asymptotic optimality of JMA for high-dimensionallinear models and generalized linear models. \( \text{Zhao et al., 2016} \) broadened \( \text{Ando}
and Li, 2014\)’s scope of analysis to dependent data. \( \text{Zhang and Wang, 2019; Fang et al., 2019,}
and \( \text{Feng et al., 2021} \) established asymptotic optimality for MA in nonparametric,
missing data, and nonlinear models, respectively.

However, most existing literature mainly focuses on optimal properties (e.g., asymptotic
efficiency) of MS or MA in their own terms. Although many successful empirical advance-
ments in MA have been demonstrated (see, e.g., \( \text{Magnus and Luca, 2016; Moral-Benito,}
2015; Steel, 2020 \)), theoretical investigations comparing MS and MA are still lacking. Re-
cently, \( \text{Peng and Yang, 2021} \) made a seminal contribution to this question. They studied the
foundational matter that compares the oracle/optimal MS with MA procedures in a nested
model setting with series expansion and have some remarkable findings. However, a limit
of Peng and Yang (2021) is that their study was built with three restrictions: orthonormal design, homoscedastic and independent random errors, and non-sparse coefficients, which could make the study is not applicable in applications. The goal of the current paper is to broaden the scope of analysis of Peng and Yang (2021) to a general model setting and to answer more important questions. Specifically, our main contributions are as follows.

(i) Without the three restrictions aforementioned, we answer the questions: does MA offer a significant improvement over MS? If it can happen, when? Moreover, we partition the predictor variables into groups and the group size is allowed to be larger than 1, which leads to a more general nested model framework than that in Peng and Yang (2021). We define a sequence of indices for grouped variables and find that its decaying order determines when MA is substantially better than MS. As a result, the analysis of Peng and Yang (2021) becomes a special case of ours. In finite simulation studies, we compare the performance of MMA or JMA with several MS methods, including AIC, BIC, and LOO-CV. The simulation results support our theoretical findings.

(ii) In MA literature, the MA weights could be chosen from three different weight sets, e.g., the unit simplex (Wan et al., 2010; Zhang et al., 2013), the unit hypercube (Ando and Li, 2014, 2017), and the discrete weight set (Hansen, 2007; Hansen and Racine, 2012). We further broaden the scope of our work to compare MAs with the weights belonged to these three weight sets.

The rest of the paper is organized as follows. Section 2 provides model setting and four important questions to be answered. Section 3 presents the main results about the comparison of MS and MA. Section 4 considers the comparison of MAs with three different weight sets. Section 5 provides two examples to verify the theoretical results. Section 6 presents the results of finite sample simulations. Section 7 concludes. The proofs of theorems, corollaries, and a lemma are relegated to the Appendix. Supplementary materials contain some additional theoretical results and simulation studies.
2 Model Setting and Questions

Consider the model
\[ y_i = \mu_i + \varepsilon_i = \sum_{j=1}^{p_n} x_{ij} \beta_j + \varepsilon_i, \quad i = 1, \ldots, n, \quad (2.1) \]
where \( \varepsilon_1, \ldots, \varepsilon_n \) are random errors, \( x_{i1}, \ldots, x_{ip_n} \) are nonstochastic predictor variables, and \( p_n \) \((p_n < n) \) is the number of the predictors. In matrix notation, (2.1) can be written as
\[ y = \mu + \varepsilon, \]
where \( y = (y_1, \ldots, y_n)^\top \), \( \mu = (\mu_1, \ldots, \mu_n)^\top \), and \( \varepsilon = (\varepsilon_1, \ldots, \varepsilon_n)^\top \). We assume that \( E(\varepsilon) = 0 \) and \( \text{Cov}(\varepsilon) = \Omega \), where \( \Omega \) is a positive definite matrix. In the current paper, we use bold forms to denote vectors or matrices.

Following [Hansen (2007, 2014), Feng and Liu (2020), and Zhang et al. (2020)], we consider the nested models, where the \( m \)th model using the first \( \nu_m \) predictor variables, such that
\[ 0 = \nu_0 < \nu_1 < \nu_2 < \cdots < \nu_{q_n} = p_n, \]
and \( q_n \) is a positive integer. This nested framework essentially requires that the predictor variables are partitioned into \( q_n \) groups and the grouped predictors are ordered, where the \( m \)th group of predictors is \( \{x_{i,\nu_{m-1}+1}, \ldots, x_{i,\nu_m}\} \) and its size is \( \nu_m - \nu_{m-1} \) for \( m = 1, \ldots, q_n \).

Because some model screening procedures may be implemented prior to MS or MA, without loss of generality, we use the first \( M_n \) \((2 \leq M_n \leq q_n) \) nested candidate models for MS and MA. Let \( X_m \) be the \( n \times \nu_m \) design matrix of the \( m \)th candidate model. We assume \( X_m \) is full of rank for any \( m \in \{1, \ldots, M_n\} \). Then, under the \( m \)th model, the estimator of \( \mu \) is
\[ \hat{\mu}_m = X_m(X_m^\top X_m)^{-1}X_m^\top y \equiv P_m y, \]
where \( P_m = X_m(X_m^\top X_m)^{-1}X_m^\top \) is the hat matrix. A MS method selects an index (say \( m^* \)) from the index set \( \mathcal{H}_n = \{1, \ldots, M_n\} \) and estimate \( \mu \) by \( \hat{\mu}_{m^*} \), using the selected model. Let \( w = (w_1, \ldots, w_{M_n})^\top \) be a weight vector belonging to the unit simplex of \( \mathbb{R}^{M_n} \):
\[ \mathcal{W}_n = \left\{ w \in [0, 1]^{M_n} : \sum_{m=1}^{M_n} w_m = 1 \right\}. \]
Then, the MA estimator of \( \mu \) with weight vector \( w \) is
\[ \hat{\mu}(w) = \sum_{m=1}^{M_n} w_m \hat{\mu}_m = \sum_{m=1}^{M_n} w_m P_m y \equiv P(w) y. \]
where \( P(\mathbf{w}) = \sum_{m=1}^{M_n} w_m \mathbf{p}_m \). The measurement of estimation accuracy is the squared prediction risk, which is defined as \( R_n(m) = E\{L_n(m)\} \) and \( R_n(\mathbf{w}) = E\{L_n(\mathbf{w})\} \) for MS and MA, respectively, where

\[
L_n(m) = \| \hat{\mu}_m - \mu \|^2 \quad \text{and} \quad L_n(\mathbf{w}) = \| \hat{\mu}(\mathbf{w}) - \mu \|^2
\]

are the squared prediction loss for MS and MA, respectively, and \( \| \cdot \|^2 \) is the squared Euclidean norm.

Let \( m_n^* \) be the oracle optimal model index that minimizes \( R_n(m) \) in \( \mathcal{H}_n \) and let \( \mathbf{w}_n^* \) be the oracle optimal weights that minimizes \( R_n(\mathbf{w}) \) in \( \mathcal{W}_n \). We assume that \( m_n^* \) and \( \mathbf{w}_n^* \) are unique. Note that we can not apply \( m_n^* \) and \( \mathbf{w}_n^* \) in practice, since they are unknown. But using the asymptotically optimal MS and MA procedures mentioned in Section 1, we can select a model index \( \hat{m}_n \) and weights \( \hat{\mathbf{w}}_n \), respectively, in the sense that

\[
\frac{R_n(\hat{m}_n)}{R_n(m_n^*)} \xrightarrow{P} 1 \quad \text{and} \quad \frac{R_n(\hat{\mathbf{w}}_n)}{R_n(\mathbf{w}_n^*)} \xrightarrow{P} 1,
\]

(2.2)

where \( \xrightarrow{P} \) denotes convergence in probability. All limiting processes are studied with respect to \( n \to \infty \). Note that in (2.2), \( \hat{m}_n \) and \( \hat{\mathbf{w}}_n \) are directly plugged in the expressions \( R_n(m) \) and \( R_n(\mathbf{w}) \). [Zhang et al. (2020)] provided a new type of asymptotical optimality as follows:

\[
\frac{E\{L_n(\hat{m}_n)\}}{R_n(m_n^*)} \to 1 \quad \text{and} \quad \frac{E\{L_n(\hat{\mathbf{w}}_n)\}}{R_n(\mathbf{w}_n^*)} \to 1,
\]

(2.3)

where the randomness of \( \hat{m}_n \) and \( \hat{\mathbf{w}}_n \) are taken into account.

Since MS is a special case of MA with weights concentrating on a single model, it is obvious that \( R_n(m_n^*) \geq R_n(\mathbf{w}_n^*) \). The first task of this paper is essentially on improvability of the oracle regression model \( m_n^* \) by the oracle MA. Let \( \Delta_n = R_n(m_n^*) - R_n(\mathbf{w}_n^*) \) denote the potential risk reduction of the oracle MA compared to the oracle MS. We first the following two key questions:

Q1. Can \( R_n(\mathbf{w}_n^*) \) bring in a smaller order than \( R_n(m_n^*) \), i.e. \( R_n(\mathbf{w}_n^*)/R_n(m_n^*) = o(1) \) happen?

Q2. Is \( \Delta_n \) a substantial reduction relative to \( R_n(m_n^*) \) or actually negligible? If both can happen, when is the MA substantially better than MS?
Remark 1. Write $x_j = (x_{1j}, \ldots, x_{nj})^T$, $j = 1, \ldots, p_n$. The vectors $x_1, \ldots, x_{p_n}$ are said to be orthonormal if

$$
\frac{1}{n} \sum_{i=1}^{n} x_{ij}^2 = 1 \quad \text{and} \quad \sum_{i=1}^{n} x_{ij} x_{ik} = 0, \quad 1 \leq j \neq k \leq p_n.
$$

(2.4)

Note that (2.4) is satisfied for a nonparametric regression with orthonormal series expansion. Peng and Yang (2021) has answered Questions Q1 and Q2 under the assumption that the predictors are orthonormal (i.e., (2.4) holds), and the error $\varepsilon_i$’s are homoscedastic and independent, which can be restrictive for some applications. In the current paper, we answer the same questions in a more general model setting without the above assumptions. Moreover, Peng and Yang (2021) used the typical nested framework $\nu_m = m$, which is also relaxed in the current paper.

In addition to the weight set $W_n$, there are other two popular weight sets in MA literature: the unit hypercube

$$
Q_n = \{ w \in [0, 1]^M : 0 \leq w_m \leq 1 \}
$$

and the discrete weight set

$$
W_n(N) = \left\{ w : w_m \in \left\{ 0, \frac{1}{N}, \frac{2}{N}, \ldots, 1 \right\}, \sum_{m=1}^{M} w_m = 1 \right\}
$$

for a fixed positive integer $N$. The weight set $Q_n$ removes the restriction of weights from adding up to 1 in $W_n$. Among MA literature, Ando and Li (2014) used this weight set to study the optimal MA for the first time in a high-dimensional linear regression setting. Recently, this weight set was further carried to other regression models, e.g., high-dimensional generalized linear model (Ando and Li, 2017), high-dimensional quantile regression (Wang et al., 2021), and high-dimensional survival analysis (He et al., 2020; Yan et al., 2021). In MA literature, the discrete set $W_n(N)$ is often only considered to establish some asymptotic theories of MA for technical convenience; see, e.g., Hansen (2007), Hansen and Racine (2012), and Fang and Liu (2020). In practice, different weight sets can produce different results, hence the comparisons of MA with the weight sets are very important. In literature, they are compared by numerical examples; see, for example, Ando and Li (2014) and Wang
et al. (2021). The next task of the current paper is on the theoretical comparison of MA with the weights belonging to different weight sets.

Let \( \tilde{w}_n^* \) and \( w_{n,N}^* \) be the oracle optimal weights that minimizes \( R_n(w) \) in \( Q_n \) and \( W_n(N) \), respectively. We assume that \( \tilde{w}_n^* \) and \( w_{n,N}^* \) are unique. Obviously, \( R_n(\tilde{w}_n^*) \leq R_n(w_n^*) \leq R_n(w_{n,N}^*) \) since \( W_n(N) \subset W_n \subset Q_n \). It implies that the weight relaxation could possibly bring in a smaller optimal risk of MA and the restriction of the weight set \( W_n \) to \( W_n(N) \) could lead to a larger optimal risk of MA. However, it is unclear that whether the risk reduction of optimal MA by relaxing the weight set \( W_n \) to \( Q_n \) is substantial and whether the risk increment of optimal MA by restricting the weight set \( W_n \) to \( W_n(N) \) is substantial. Since \( W_n \) is widely used, we use \( R_n(w_n^*) \) as a benchmark for the comparisons. Therefore, we consider the other two key issues as follows:

Q3. Is \( R_n(w_n^*) - R_n(\tilde{w}_n^*) \) a substantial reduction relative to \( R_n(w_n^*) \) or actually negligible? If both can happen, when is \( \tilde{w}_n^* \) substantially better than \( w_n^* \)?

Q4. Is the risk increment \( R_n(w_{n,N}^*) - R_n(w_n^*) \) substantial relative to \( R_n(w_n^*) \) or actually negligible? If both can happen, when is \( w_n^* \) substantially better than \( w_{n,N}^* \)?

The answers to Questions Q1 and Q2 broaden the scope of Peng and Yang (2021)’s work on advantage of MA over MS. The answers to Questions Q3 and Q4 provide a previously unavailable insight on relative strengths of MA with these three weight sets.

Throughout this paper, we will use the following symbols. For two nonstochastic positive sequences \( a_n \) and \( b_n \), \( a_n \succeq b_n \) means \( b_n = O(a_n) \), and \( a_n \asymp b_n \) means both \( a_n \succeq b_n \) and \( b_n \succeq a_n \). Also, \( a_n \sim b_n \) means that \( a_n/b_n \to 1 \). For two stochastic sequences \( a_n \) and \( b_n \), \( a_n \preceq_p b_n \) means that \( a_n = O(b_n)\{1 + o_p(1)\} \) and \( b_n = O(a_n)\{1 + o_p(1)\}; \) \( a_n \sim_p b_n \) means that \( a_n/b_n \to_p 1 \). Let \( \lfloor a \rfloor \) be the greatest integer less than or equal to \( a \). Let \( \lambda_{\min}(\Omega) \) and \( \lambda_{\max}(\Omega) \) be the minimum and maximum eigenvalues of \( \Omega \), respectively.
3 Comparisons of MS and MA Procedures

In this section, the goal is to answer Questions Q1 and Q2. We first introduce some important notations and assumptions. Then, we theoretically investigate the comparison of the oracle optimal model $m^*_n$ and the oracle MA in Subsection 3.2. Last, we extend the obtained results to compare two specific asymptotically optimal MS and MA procedures in Subsection 3.3.

3.1 Grouped Variable Importance

In this subsection, we introduce a notation to measure the importance of each grouped predictors, whose decaying order determines when MA is substantially better than MS that will be shown in Subsection 3.2. Let $X^c_m$ be the $n \times (p_n - \nu_m)$ design matrix that consists of the predictors excluded from the $m$th model. Let $\beta_m = (\beta_1, \ldots, \beta_{\nu_m})^T$ and $\beta^c_m = (\beta_{\nu_m+1}, \ldots, \beta_{p_n})^T$. Then, $\mu = X_m \beta_m + X^c_m \beta^c_m$. For convenience, we further assume $X_m$ is full of rank for any $m \in \{M_n + 1, \ldots, q_n\}$. For the $m$th model ($m = 1, \ldots, q_n$), define

$$\theta_{n,m} = \frac{\beta^c_m X^c_{m-1} (I_n - P_{m-1}) X^c_{m-1} \beta^c_{m-1} - \beta^c_m X^c_{m-1} (I_n - P_m) X^c_m \beta^c_m}{\text{tr}\{(P_m - P_{m-1})\Omega\}}, \quad (3.1)$$

where $P_0 = 0$. Since the two terms in the numerator of (3.1) measure the importance of the remaining predictors after excluding from the $(m - 1)$th model and the $m$th model, respectively, $\theta_{n,m}$ can be regarded as the importance of the $m$th group of variable in some sense. Therefore, we term $\theta_{n,m}$ as the grouped variable importance (GVI).

Next, we impose additional assumptions for the model (2.1) to obtain simple forms of GVI as follows.

Case 1 (Orthonormal design) If the orthonormal design assumption (2.4) is satisfied, it is easy to show that $\beta^c_m X^c_m (I_n - P_m) X^c_m \beta^c_m = n \| \beta^c_m \|^2$. Then, $\theta_{n,m}$ reduces to

$$\theta_{n,m} = \frac{\sum_{j=\nu_m+1}^{\nu_m} \beta_j^2}{\text{tr}\{(P_m - P_{m-1})\Omega\}}.$$

Case 2 (Homoscedastic and uncorrelated errors) If the error terms are homoscedastic and uncorrelated with variance $\sigma^2 > 0$, it is easy to see that $\text{tr}\{(P_m - P_{m-1})\Omega\} = \sigma^2 (\nu_m -
\( \nu_{m-1} \). Then, \( \theta_{n,m} \) reduces to
\[
\theta_{n,m} = \frac{\beta_{m-1}^c X_{m-1}^c (I_n - P_{m-1}) X_m^c \beta_{m-1} - \beta_m^c X_m^c (I_n - P_m) X_m^c \beta_m}{n \sigma^2 (\nu_m - \nu_{m-1})}.
\]

**Case 3 (Orthonormal design and homoscedastic and uncorrelated errors)** If the orthonormal design assumption (2.4) is satisfied and the error terms are homoscedastic and uncorrelated with variance \( \sigma^2 > 0 \), then \( \theta_{n,m} \) has a simple form
\[
\theta_{n,m} = \sum_{j=\nu_{m-1}+1}^{\nu_m} \frac{\beta_j^2}{\sigma^2 (\nu_m - \nu_{m-1})}.
\]

**Case 4 (Model setting of Peng and Yang (2021))** In the model setting of Peng and Yang (2021), i.e., under the assumptions of the orthonormal design (2.4), the homoscedastic and uncorrelated errors with variance \( \sigma^2 > 0 \), and the typical nested framework \( \nu_m = m \), \( \theta_{n,m} \) reduces to
\[
\theta_{n,m} = \frac{\beta_m^2}{\sigma^2}.
\]

From these cases (especially, Cases 1, 3, and 4), the numerator of \( \theta_{n,m} \) is determined by the coefficients of the variables in the \( m \)th group, which further means that \( \theta_{n,m} \) is a measure of the grouped variable importance. In the following remark, we provide another explanation for \( \theta_{n,m} \).

**Remark 2 (Another explanation for \( \theta_{n,m} \)).** By some simple calculations, we can get a more simple form for \( \theta_{n,m} \) as follows
\[
\theta_{n,m} = \frac{n^{-1} \mu^\top (P_m - P_{m-1}) \mu}{\text{tr}(P_m \Omega)}.
\]

In the first formula of Appendix A.1, we show that the risk of \( \hat{\mu}_m \) is
\[
R_n(m) = E \| \hat{\mu}_m - \mu \|^2 = \text{tr} \left\{ (E \hat{\mu}_m - \mu)(E \hat{\mu}_m - \mu)^\top \right\} + \text{tr} \{ \text{var}(\hat{\mu}_m) \} = \mu^\top (I_n - P_m) \mu + \text{tr}(P_m \Omega),
\]
where \( \mu^\top (I_n - P_m) \mu \) is the trace of the squared bias term of \( \hat{\mu}_m \) and \( \text{tr}(P_m \Omega) \) is the trace of the variance term of \( \hat{\mu}_m \), which are non-increasing and increasing in \( m \), respectively,
because of the nested framework of candidate models. Therefore, by (3.2), the numerator and denominator of $\theta_{n,m}$ are the decrement of the squared bias scared by $n$ and the increment of the variance of risks, respectively, when adding the $m$th group of predictors to the $(m-1)$th model. When $\Omega = \sigma^2 I_n$ and the size of groups is fixed (say $\nu^*$), the increment of the variance of risks is fixed to be $\nu^* \sigma^2$.

We now impose the following two assumptions for the model (2.1), which are commonly used in the MA literature.

**Assumption 1.** $\|\mu\|^2/n = O(1)$.

**Assumption 2.** There are constants $0 < c_1 \leq c_2 < \infty$ such that $c_1 < \lambda_{\min}(\Omega) \leq \lambda_{\max}(\Omega) < c_2$.

Assumption 1 requires the average of $\mu^2_i$ is bounded. Assumption 2 excludes the degeneracy and divergence of the error terms. Similar assumptions can be found in Wan et al. (2010), Zhang et al. (2013), and Liu et al. (2016). Since $P_m P_l = P_{\min(m,l)}$ in the nested model setting, it can be easily verified that $P_m - P_{m-1}$ is a symmetric idempotent matrix, which, together with Assumption 1 yields that $0 \leq n^{-1} \mu^\top (P_m - P_{m-1}) \mu \leq \|\mu\|^2/n < \infty$. Using Assumption 2, we have

$$0 < c_1 (\nu_m - \nu_{m-1}) < \text{tr}\{(P_m - P_{m-1}) \Omega\} < c_2 (\nu_m - \nu_{m-1}).$$

By (3.2) and the truth that $P_m - P_{m-1}$ is a symmetric idempotent matrix, we know that

$$0 \leq \theta_{n,m} < \infty$$

for any $n$ and $m = 1, \ldots, q_n$.

We further impose an assumption on $\theta_{n,m}$ as follows.

**Assumption 3.** For each sufficiently large $n$, $\{\theta_{n,m} : m = 1, \ldots, q_n\}$ is a non-increasing sequence.

Assumption 3 is an extension of Assumption 1 of Peng and Yang (2021). The non-increasing ordering of $\{\theta_{n,m}\}_{m=1}^{q_n}$ can give us a convenience to characterize the unknown
optimal model index \( m^*_n \) and weights \( \mathbf{w}^*_n, \ \bar{\mathbf{w}}^*_n, \) and \( \mathbf{w}^*_{n,N} \), and essentially requires that the predictors are groupwise ordered from the most important to the least important, i.e, the ordering of grouped variables is “correct”. However, different from Peng and Yang (2021) where the sequence \( \{\theta_{n,m} : m = 1, \ldots, q_n\} \) required to be positive, the current paper allows some components in the sequence to be equal to zeros, i.e., we allow some totally unimportant variables. For the aforementioned Cases 3-4, it means we allow some kind of sparsity of coefficients, which is an important property especially for high-dimensional problems. Under Assumption 3, let \( d_n = \max\{m \in \{1, \ldots, q_n\} : \theta_{n,m} > 0\} \) be the number of important groups of predictors. If \( d_n < q_n \), the \( m \)th group of predictors is not important for \( m = d_n + 1, \ldots, q_n \).

Next, we make the following assumptions.

**Assumption 4.** There exists a constant \( V \geq 1 \) which does not depend on \( m \) and \( n \), such that \( \max_{1 \leq m \leq d_n}(\nu_m - \nu_{m-1}) \leq V \) holds uniformly in large enough \( n \).

**Assumption 5.** For any fixed \( m \in \{1, \ldots, d_n\} \), there exist constants \( \bar{\theta}_m > 0 \) and \( K_m > 0 \)
such that $\theta_{n,m} \geq \bar{\theta}_m$ for any $n \geq K_m$.

**Assumption 6.** For each sufficiently large $n$, $R_n(m)$ is first decreasing and then increasing when $m$ varies from 1 to $d_n$.

Assumption 4 means that when the predictors are partitioned into groups described in Section 2, the sizes of all important groups do not grow to infinity as $n$ increases. Hansen (2014) and Zhang et al. (2016a) also made assumptions on group sizes for the comparison of the risks of estimators by the full model and the MMA. Assumption 5 basically eliminates the case that $\theta_{n,m}$ goes to zero as $n$ increases for any fixed $m \in \{1, \ldots, d_n\}$. Thus, it excludes the local-to-zero asymptotic framework with fixed dimensions considered by Hjort and Claeskens (2003) and Liu (2015). Note that in the model setting of Peng and Yang (2021), Assumptions 4–5 are obviously satisfied. Assumption 6 essentially prevents $d_n$ from being too small. For example, when $d_n \equiv d_0$ is fixed as $n \to \infty$ and Assumptions 2 and 5 hold, by (A.1) in the Appendix,

$$R_n(m) - R_n(m - 1) = n\text{tr}\{(P_m - P_{m-1})\Omega\} \left(\frac{1}{n} - \theta_{n,m}\right) \leq n\text{tr}\{(P_m - P_{m-1})\Omega\} \left(\frac{1}{n} - \bar{\theta}_m\right) < 0$$

for $m = 2, \ldots, d_0$ and each sufficiently large $n$, which implies that $R_n(m)$ is decreasing on $\{1, \ldots, d_0\}$ for each sufficiently large $n$ and thus Assumption 6 is not satisfied. Under Assumptions 3 and 5, Assumption 6 is satisfied when $\theta_{n,d_n} < 1/n$ for each sufficiently large $n$, which is derived as follows. For a sufficiently large $n$, from Assumptions 3 and 5 and $\theta_{n,d_n} < 1/n$, there exists a $m'_n \in \{2, \ldots, d_n - 1\}$ such that $\theta_{n,m'_n} > 1/n \geq \theta_{n,m'_n+1}$. Therefore, when $m = 2, \ldots, m'_n$,

$$R_n(m) - R_n(m - 1) \leq n\text{tr}\{(P_m - P_{m-1})\Omega\} \left(\frac{1}{n} - \theta_{n,m'_n}\right) < 0;$$

when $m = m'_n + 1, \ldots, d_n$,

$$R_n(m) - R_n(m - 1) \geq n\text{tr}\{(P_m - P_{m-1})\Omega\} \left(\frac{1}{n} - \theta_{n,m'_n+1}\right) \geq 0;$$
and \( R_n(d_n) - R_n(d_n - 1) > 0 \), which together imply that \( R_n(m) \) is decreasing in \( m \in \{1, \ldots, m'_n\} \) and increasing in \( m \in \{m'_n, \ldots, d_n\} \). Assumption 6 also implies that \( R_n(m) \) is first decreasing and then increasing when \( m \) increases from 1 to \( q_n \) for each sufficiently large \( n \). In the derivation of (A.2) in Peng and Yang (2021), they also used this assumption.

Let \( m^{**}_n = \arg \min_{m \in \{1, \ldots, q_n\}} R_n(m) \) be the global optimal model index. We assume that \( m^{**}_n \) is unique. Note that \( m^{**}_n \) may not equal to \( m^*_n \) since the number of candidate models \( M_n \) may be too small to include the \( m^{**}_n \)th model. In fact, under Assumption 6,

\[
m^*_n = \min\{M_n, m^{**}_n\} = \begin{cases} M_n, & \text{if } M_n < m^{**}_n; \\ m^{**}_n, & \text{if } M_n \geq m^{**}_n. \end{cases}
\]

see Figure 1 which shows two typical situations for \( m^*_n \). Peng and Yang (2021) compared MS and MA under the assumption that \( M_n \) is large enough to include \( m^{**}_n \), i.e., \( M_n \geq m^{**}_n \). However, there is a lack of considering on the comparison of MS and MA when \( M_n < m^{**}_n \). In this paper, we also relax this assumption and investigate the impact of \( M_n \) on the comparison of MS and MA.

In Subsections 3.2–3.3, we shall show that the number of candidate models \( M_n \) and the decaying order of \( \{\theta_{n,m}\}_{m=1}^{d_n} \) determine when MA is substantially better than MS.

### 3.2 A Comparison of Oracle Optimal MS and MA

In this subsection, we answer Questions Q1 and Q2, that is we compare the risks of optimal MS and MA estimators. We begin with the following theorem on the order relationship of \( R_n(m^*_n) \) and \( R_n(w^*_n) \), which provides an answer to Question Q1.

**Theorem 1 (Answer to Question Q1).** Suppose that Assumptions 1-3 and 6 hold. Then, for any sufficiently large \( n \),

\[
R_n(w^*_n) \geq \frac{1}{2} R_n(m^*_n).
\]

Moreover, the risks using \( m^*_n \) and \( w^*_n \) have the same order, i.e.,

\[
R_n(m^*_n) \asymp R_n(w^*_n).
\]
Note that Theorem 1 needs not any restriction on the number of candidate models $M_n$, while Peng and Yang (2021) restricted $M_n \geq m_n^{**}$. Inequality (3.3) leads to $\Delta_n \leq \frac{1}{2} R_n(m_n^*)$ for sufficiently large $n$, which implies that the potential risk reduction of MA compared to MS does not exceed half of optimal risk of MS. Equation (3.4) indicates that while MA has a smaller optimal risk than MS, MA actually cannot reduce the increasing rate (or improve the decreasing rate) of risk by the optimal MS. Thus, even if the oracle model based on MS can be improved by MA, the potential advantage of MA in risk reduction is limited in terms of the increasing/decreasing rate.

We now turn our attention to Question Q2. We first present the following theorem on some elementary properties of the global optimal model index $m_n^{**}$, $R_n(m_n^*)$, and $R_n(w_n^*)$, which are important for the subsequent analysis.

**Theorem 2.** Suppose that Assumptions 1–6 are satisfied. Then,

(i) $m_n^{**} \to \infty$ as $n \to \infty$;

(ii) $R_n(m_n^*) \to \infty$ and $R_n(w_n^*) \to \infty$ as $n \to \infty$.

Theorem 2(i) indicates that the index of the global optimal model diverges to infinity as $n \to \infty$ under some mild assumptions. For applications, this result tells us that a diverging dimension should be utilized to achieve a promising MS performance. Theorem 2(ii) means that the smallest risks of MS and MA grow to infinity as the sample size $n$ increases. Note that Theorem 2(ii) does not require the restriction $M_n \geq m_n^{**}$, but this restriction is used in Peng and Yang (2021).

To investigate the impact of the number of candidate models $M_n$ on the comparison of MS and MA, we consider the following two conditions for $M_n$.

**Condition M1** (Too Small $M_n$). $\lim_{n \to \infty} M_n/m_n^{**} = 0$.

**Condition M2** (Large Enough $M_n$). There exists a constant $c > 0$ such that $M_n/m_n^{**} \geq c$ when $n$ is large enough.
By Theorem 2(i), under Assumptions 1-6, Condition M1 holds when $M_n$ is fixed or diverges to infinity more slowly than $m_n^{**}$ as $n \to \infty$. Condition M2 holds when $M_n \geq m_n^{**}$ considered by Peng and Yang (2021) or $M_n < m_n^{**}$ but $M_n$ has the same order with $m_n^{**}$. Next, we successively explore the degree of improvement $\Delta_n/R_n(m_n^*)$ by the following theorems under Conditions M1 and M2.

**Theorem 3 (Answer to Question Q2 under Condition M1).** Suppose that Assumptions 1-6 hold. Under Condition M1,

$$\Delta_n = o\{R_n(m_n^*)\}.$$  

Theorem 3 implies that when the number of candidate models $M_n$ is fixed or diverges to infinity more slowly than $m_n^{**}$ as $n \to \infty$, MA has no essential advantage over MS, which again indicates that in applications, an enough large number of candidate models should be utilized. Note that Theorem 3 does not require any assumption of the decaying order of $\{\theta_{n,m}\}_{m=1}^d$.

Furthermore, when Condition M2 holds, we explore the degree of improvement $\Delta_n/R_n(m_n^*)$ by the following theorem under sensible conditions on $\theta_{n,m}$, which provides an answer to Question Q2 under Condition M2. The answer depends on the decaying order of $\{\theta_{n,m}\}_{m=1}^d$.

**Condition A1** (Slowly Decaying $\{\theta_{n,m}\}_{m=1}^d$). There exist constants $k > 1$, $0 < \delta \leq \eta < 1$ with $k\eta < 1$, and $K > 0$ such that for every integer sequence $\{l_n\}$ satisfying $\lim_{n \to \infty} l_n = \infty$,

$$\delta \leq \theta_{n,\lfloor kl_n \rfloor}/\theta_{n,l_n} \leq \eta$$

for any $n \geq K$.

**Condition A2** (Fast Decaying $\{\theta_{n,m}\}_{m=1}^d$). For every constant $k > 1$ and every integer sequence $\{l_n\}$ satisfying $\lim_{n \to \infty} l_n = \infty$,

$$\lim_{n \to \infty} \theta_{n,\lfloor kl_n \rfloor}/\theta_{n,l_n} = 0.$$ 

In the model setting of Peng and Yang (2021), since $\theta_{n,m} = \beta_m^2/\sigma^2$, Conditions A1–A2 are equivalent to the conditions 1–2 of Peng and Yang (2021), respectively.
Theorem 4 (Answer to Question Q2 under Condition M2). Suppose that Assumptions 1-6 and Condition M2 holds. Under Condition A1, we have

\[ \Delta_n \simeq R_n(m^*_n). \]

Under Condition A2, we have

\[ \Delta_n = o\{R_n(m^*_n)\}. \]

From Theorems 1 and 4 under Condition A1,

\[ \frac{1}{2} \leq \liminf_{n \to \infty} \frac{R_n(w^*_n)}{R_n(m^*_n)} \leq \limsup_{n \to \infty} \frac{R_n(w^*_n)}{R_n(m^*_n)} \leq 1 - c^* \]

for some \( c^* \in (0, 1/2) \); and under Condition A2, \( R_n(w^*_n) \sim R_n(m^*_n) \). Therefore, when the number of candidate models \( M_n \) is large enough, there is a phase transition for the advantage of MA over MS. When \( \theta_{n,m} \) decays slowly in \( m \), the oracle MA can reduce the optimal risk of MS by a substantial fraction; when \( \theta_{n,m} \) decays fast in \( m \), MA has no real advantage over MS.

To gain a better understanding of Conditions A1–A2, we make the following more simple conditions (i.e., Assumption 7 and Conditions B1–B2), which imply Conditions A1–A2 by Lemma 1 below.

Assumption 7. There exists a sequence \( \theta^*_m > 0 \) for \( m = 1, \ldots, d_n \) such that

\[ \sup_{1 \leq m \leq d_n} \left\| \frac{\theta_{n,m}}{\theta^*_m} - 1 \right\| \to 0 \text{ as } n \to \infty. \]

Condition B1 (Slowly Decaying \( \theta^*_m \)). There exist constants \( k > 1 \) and \( 0 < \delta^* \leq \eta^* < 1 \) with \( k\eta^* < 1 \) such that \( \delta^* \leq \theta^*_m / \theta^*_m \leq \eta^* \) when \( m \) is large enough.

Condition B2 (Fast Decaying \( \theta^*_m \)). For every constant \( k > 1 \), \( \lim_{m \to \infty} \theta^*_m / \theta^*_m = 0 \).

Lemma 1. Suppose that Assumption 7 holds. Then, Conditions B1–B2 imply Conditions A1–A2, respectively.
Assumption 7 implies that \( \lim_{n \to \infty} \theta_{n,m} = \theta_m^* \) for any fixed \( m \). Thus, Assumption 7 can lead to Assumption 5 by taking \( \bar{\theta}_m = \theta_m^*/2 \). Condition B1 is satisfied for \( \theta_m^* \sim m^{-2\alpha} \) or slightly more generally for \( \theta_m^* \sim m^{-2\alpha}(\log m)^\beta \) with constants \( \alpha > 1/2 \) and \( \beta \in \mathbb{R} \). Condition B2 is satisfied for the exponential-decay case, that is, \( \theta_m^* \sim \exp(-cm) \) for some \( c > 0 \). These two types of decaying rates are commonly used in the literature. For example, in the research of infinite-order autoregressive (AR) models, Ing and Wei (2005), Ing (2007), and Liao et al. (2021) considered the exponential-decay and algebraic-decay cases for the AR coefficients, which are described in our context as follows:

(i) Exponential-decay case: \( C_1 m^{-\tau_1} e^{-cm} \leq \theta_m^* \leq C_2 m^{\tau_1} e^{-cm} \), where \( C_1, C_2, \tau_1, \) and \( c \) are some constant with \( C_2 \geq C_1 > 0, \tau_1 \geq 0, \) and \( c > 0 \).

(ii) Algebraic-decay case: \( (C_3 - C_4 m^{-\tau_2})m^{-\bar{\alpha}} \leq \theta_m^* \leq (C_3 + C_4 m^{-\tau_2})m^{-\bar{\alpha}} \), where \( C_3, C_4, \tau_2, \) and \( \bar{\alpha} > 1 \) are some positive constants.

It can be easily verified that the exponential-decay case (i) and the algebraic-decay case (ii) satisfy Condition B2 and Condition B1, respectively.

### 3.3 A Comparison of Two Specific MS and MA Procedures

Up to now, the theoretical results of Theorems 1 and 3–4 mainly focus on the comparison of oracle optimal MS and MA, not directly on the comparison of two specific MS and MA procedures. Fortunately, by using (2.2) and (2.3), we can do the latter comparison by connecting the feasible risks (when using a selected model index or weights from some methods) and infeasible risks (when using the oracle model index or weights). In literature, the proof of asymptotic efficiency (or optimality) of MS and MA requires the smallest risks of MS and MA (i.e., \( R_n(m_n^*) \) and \( R_n(w_n^*) \) in our notations) to grow to infinity as the sample size increases, respectively. Both have been verified in Theorem 2(ii) under Assumptions 1–6.

Let \( \hat{m}_n \) and \( \hat{w}_n \) be the selected model index and chosen weights based on asymptotically optimal MS and MA methods, respectively. Then, we have the following two consequences.
Corollary 1. Suppose that Assumptions 1-6 hold, and \( \hat{m}_n \) and \( \hat{w}_n \) are asymptotically optimal in the sense of (2.2), i.e., \( R_n(\hat{m}_n)/R_n(m^*_n) \to_p 1 \) and \( R_n(\hat{w}_n)/R_n(w^*_n) \to_p 1 \). Then,

(i) the risks using \( \hat{m}_n \) and \( \hat{w}_n \) have the same order, i.e., \( R_n(\hat{m}_n) \asymp R_n(\hat{w}_n) \);

(ii) under Conditions M2 and A1, the MA using \( \hat{w}_n \) essentially improves over the MS using \( \hat{m}_n \), i.e., \( R_n(\hat{m}_n) - R_n(\hat{w}_n) \asymp_p R_n(\hat{m}_n) \);

(iii) under Condition M1 or Conditions M2 and A2, \( \hat{m}_n \) and \( \hat{w}_n \) are asymptotically equivalent in risk, i.e., \( R_n(\hat{m}_n) \sim_p R_n(\hat{w}_n) \).

Corollary 2. Suppose that Assumptions 1-6 hold, and \( \hat{m}_n \) and \( \hat{w}_n \) are asymptotically optimal in the sense of (2.3), i.e., \( E\{L_n(\hat{m}_n)\}/R_n(m^*_n) \to 1 \) and \( E\{L_n(\hat{w}_n)\}/R_n(w^*_n) \to 1 \). Then, the results of Corollary 1 hold when \( R_n(\hat{m}_n) \), \( R_n(\hat{w}_n) \), \( \asymp_p \), and \( \sim_p \) are replaced by \( E\{L_n(\hat{m}_n)\} \), \( E\{L_n(\hat{w}_n)\} \), \( \asymp \), and \( \sim \), respectively.

Since the proofs of Corollaries 1 and 2 are similar, we only give the proof of Corollary 1 in Appendix 4.6.

4 Comparisons of MAs with Different Weight Sets

In this section, we shall compare the optimal risks of MAs when the weights belong to three weight sets: \( \mathcal{W}_n \), \( \mathcal{Q}_n \), and \( \mathcal{W}_n(N) \), which provide answers to Questions Q3–Q4.

4.1 A Comparison of MAs with Weight Sets \( \mathcal{W}_n \) and \( \mathcal{Q}_n \)

In this subsection, we focus on the comparison of the risks of MA estimators when the weights comes from \( \mathcal{W}_n \) and \( \mathcal{Q}_n \), respectively. We first present the following theorem, which provides an answer to Question Q3.

Theorem 5 (Answer to Question Q3). Suppose that Assumptions 1-6 hold. Then,

\[
R_n(w^*_n) - R_n(\tilde{w}^*_n) = o\{R_n(w^*_n)\},
\]

(i.e., \( w^*_n \) and \( \tilde{w}^*_n \) are asymptotically equivalent in risk.)
Equation (4.1) indicates that while the weight relaxation could lead to a smaller optimal risk of MA, asymptotically it does not provide any substantial benefit. Note that Theorem 5 does not require any assumptions of the number of candidate models $M_n$ and the decaying order of $\{\theta_{n,m}\}_{m=1}^{d_n}$.

Furthermore, we compare two specific asymptotically optimal MS and MA procedures, where MA weights are chosen from the weight set $Q_n$. Let $\hat{\omega}_n^Q$ be chosen weights based on a specific MA method satisfying the asymptotic optimality (2.2) or (2.3) when the total weight is not constrained (i.e., the total weight constraint $\sum_{m=1}^{M_n} w_m = 1$ is not used). For example, the asymptotic optimality (2.2) of JMA without the total weight constraint has been established by Ando and Li (2014) and Zhao et al. (2016) for independent data and dependent data, respectively. Using Theorem 5, it is easy to conclude the following corollary on a comparison of MA without the total weight constraint and MS.

**Corollary 3.** Suppose that Assumptions 1-6 hold.

(i) Assume that $\hat{\omega}_n$ and $\hat{\omega}_n^Q$ satisfy $R_n(\hat{\omega}_n)/R_n(m_n^*) \to_p 1$ and $R_n(\hat{\omega}_n^Q)/R_n(w_n^*) \to_p 1$,
then the results of Corollary 1 hold when $\hat{\omega}_n$ is replaced by $\hat{\omega}_n^Q$.

(ii) Assume that $\hat{\omega}_n$ and $\hat{\omega}_n^Q$ satisfy $E\{L_n(\hat{\omega}_n^Q)\}/R_n(m_n^*) \to 1$ and $E\{L_n(\hat{\omega}_n^Q)\}/R_n(w_n^*) \to 1$,
then the results of Corollary 2 hold when $\hat{\omega}_n$ is replaced by $\hat{\omega}_n^Q$.

### 4.2 A Comparison of MAs with Weight Sets $W_n$ and $W_n(N)$

In this subsection, we focus on the comparison of the optimal risks of MA estimators with the weights belonging to the weight sets $W_n$ and $W_n(N)$, respectively. We present the following theorem on an upper bound of $R_n(w_{n,N}^*) - R_n(w_n^*)$ and an answer to Question Q4.

**Theorem 6 (Answer to Question Q4).** Suppose that Assumptions 1-6 hold. Then, for any sufficiently large $n$,

$$R_n(w_{n,N}^*) - R_n(w_n^*) \leq \frac{1}{2N}R_n(m_n^*).$$ (4.2)
Furthermore, under Conditions M2 and A1, we have

\[ R_n(w_{n,N}^*) - R_n(w_n^*) \asymp R_n(w_n^*); \]

and under Condition M1 or Conditions M2 and A2, we have

\[ R_n(w_{n,N}^*) - R_n(w_n^*) = o\{R_n(w_n^*)\}, \]

i.e.,

\[ R_n(w_{n,N}^*) \sim R_n(w_n^*). \]

Observe that \( R_n(w_{n,1}^*) = R_n(m_n^*) \). Therefore, Theorems 1 and 3–4 are special cases of Theorem 6 with \( N = 1 \). The upper bound in (4.2) implies that for a fixed and sufficiently large sample size, \( R_n(w_{n,N}^*) \) can be made arbitrarily close to \( R_n(w_n^*) \) as \( N \) is large enough, which is expected since \( W_n(N) \) approaches \( W_n \) as close as possible by making \( N \) sufficiently large. From Theorem 6 when \( M_n \) is large enough and \( \theta_{n,m} \) decays slowly in \( m \), restricting the weight set \( W_n \) to \( W_n(N) \) can enlarge the optimal risk of MA by a substantial multiple; when \( M_n \) is too small or \( M_n \) is large enough and \( \theta_{n,m} \) decays fast in \( m \), MA restricted to the discrete weight set has no real disadvantage over MA with \( W_n \). In the Supplementary Material, we further present a comparison of MAs with nested discrete weight sets.

5 Two Examples

In this section, we provide two examples to verify the theoretical results of Theorems 3–4 and 6 whose detailed derivations are given in Appendix A.10. Given \( a, b > 0 \), the incomplete beta function is defined by

\[ B(x; a, b) = \int_0^x t^{a-1} (1 - t)^{b-1} \, dt \text{ for } 0 \leq x \leq 1. \]

In these two examples, we consider the model setting of Peng and Yang (2021), that is model (2.1) with orthonormal design assumption (2.4), homoscedastic and uncorrelated error terms and \( \nu_m = m \) for \( m = 1, \ldots, p_n \).

**Example 5.1 (Slowly Decaying \( \theta_{n,m} \)).** The true coefficients are set to \( \beta_m = m^{-\alpha} \) with \( \alpha > 1/2 \). Then, \( \theta_{n,m} = m^{-2\alpha}/\sigma^2 \) and Condition A1 is satisfied. By some simple calculations,
we can get \( m_n^{**} \sim \left( \frac{n}{\sigma^2} \right)^{\frac{1}{2}} \). We consider the following two situations on the number of candidate models \( M_n \).

(i) When \( \lim_{n \to \infty} M_n / m_n^{**} = 0 \), we have
\[
\frac{1}{n} R_n(w_{n,N}^*) \sim \frac{1}{n} R_n(w_n^*) \sim \begin{cases} 
\sum_{m=M+1}^{\infty} m^{-2\alpha}, & \text{if } M_n \equiv M \text{ is fixed as } n \to \infty, \\
\frac{M_n^{-2\alpha+1}}{2\alpha-1}, & \text{if } \lim_{n \to \infty} M_n = \infty \text{ but } M_n = o(m_n^{**}).
\end{cases}
\]
This verifies that \( R_n(w_{n,N}^*) \sim R_n(w_n^*) \) under Condition M1, which accords with Theorem 3 and the third conclusion of Theorem 6.

(ii) When \( M_n / m_n^{**} \geq \epsilon \) for some \( \epsilon > 0 \), we have
\[
\frac{1}{n} R_n(w_{n,N}^*) \leq \frac{1}{n} R_n(w_n^*) \leq n^{-\frac{2\alpha-1}{2\alpha}}.
\]
By a simple calculation, we know that \( R_n(w_{n,N}^*) - R_n(w_n^*) \) is lower bounded by \( \frac{\alpha \sigma^2}{2^{\alpha+1} \omega - 2^{\alpha+2}} \left( \frac{n}{\sigma^2} \right)^{\frac{1}{2\alpha}} \), where \( \omega = \min\{\epsilon,(2N-1)^{-\frac{1}{2\alpha}}\} \). Moreover, if \( \lim_{n \to \infty} M_n / m_n^{**} = \kappa, \kappa \in (0, \infty] \) and \( M_n = o(p_n) \), we have
\[
\lim_{n \to \infty} \frac{R_n(w_{n,N}^*)}{R_n(w_n^*)} = \frac{1}{\psi_N^* + \kappa^{-2\alpha+1} \frac{2\alpha-1}{4\alpha^2} \left[ \frac{\pi}{2\alpha} - B \left( \frac{1}{1+\kappa^2 \sigma^2}; 1 - \frac{1}{2\alpha}, \frac{1}{2\alpha} \right) \right] + \kappa^{-2\alpha} \frac{1}{2\alpha}},
\]
where \( \psi_N^* \) is defined in Appendix A.10. Furthermore, we can show that
\[
\lim_{n \to \infty} \frac{R_n(w_{n,N}^*)}{R_n(w_n^*)} < 1,
\]
which verifies that \( R_n(w_{n,N}^*) - R_n(w_n^*) \geq R_n(w_n^*) \), which accords with the first conclusion of Theorem 4 and the second conclusion of Theorem 6. Figure 2(a) plots \( \lim_{n \to \infty} \frac{R_n(w_{n,N}^*)}{R_n(w_n^*)} \) againsts \( N \in \{1, \ldots, 10\} \) for \( \kappa = 0.5, 1, 2 \) and Figure 2(b) plots \( \lim_{n \to \infty} \frac{R_n(w_{n,N}^*)}{R_n(w_n^*)} \) againsts \( \kappa \in (0, 8) \) for \( N = 1, 2, 4 \), where \( \alpha = 0.8 \), which further verifies that \( \lim_{n \to \infty} \frac{R_n(w_{n,N}^*)}{R_n(w_n^*)} < 1 \).

**Example 5.2 (Fast Decaying \( \beta_{n,m} \)).** The true coefficients are set to \( \beta_m = \exp(-cm) \) with \( c > 0 \). Then, \( \beta_{n,m} = \exp(-2cm)/\sigma^2 \) and Condition A2 is satisfied. The global optimal model should include the first \( m_n^{**} \sim \frac{1}{2\epsilon} \log \left( \frac{2\epsilon}{\sigma^2} \right) \) terms. We consider the following three situations on the number of candidate models \( M_n \).

(i) When \( \limsup_{n \to \infty} M_n / m_n^{**} < 1 \), we have
\[
\frac{1}{n} R_n(w_{n,N}^*) \sim \frac{1}{n} R_n(w_n^*) \sim \frac{\exp(-2cM_n)}{\exp(2c) - 1},
\]

\[
\text{Example 5.2 (Fast Decaying } \beta_{n,m} \text{). The true coefficients are set to } \beta_m = \exp(-cm) \text{ with } c > 0. \text{ Then, } \beta_{n,m} = \exp(-2cm)/\sigma^2 \text{ and Condition A2 is satisfied. The global optimal model should include the first } m_n^{**} \sim \frac{1}{2\epsilon} \log \left( \frac{2\epsilon}{\sigma^2} \right) \text{ terms. We consider the following three situations on the number of candidate models } M_n. \]

(i) When } \limsup_{n \to \infty} M_n / m_n^{**} < 1, \text{ we have }
\[
\frac{1}{n} R_n(w_{n,N}^*) \sim \frac{1}{n} R_n(w_n^*) \sim \frac{\exp(-2cM_n)}{\exp(2c) - 1},
\]

\[
21
\]
which verifies that $R_n(w^*_{n,N}) \sim R_n(w^*_n)$ under Condition M1 and accords with Theorem 3 and the third conclusion of Theorem 6.

(ii) When $M_n < m^*_n$ for any sufficiently large $n$ but $\lim_{n \to \infty} M_n/m^*_n = 1$, we have

$$\frac{1}{n} R_n(w^*_{n,N}) \sim \frac{1}{n} R_n(w^*_n) \sim \frac{1}{2c} \frac{\sigma^2}{n} \log \left( \frac{n}{\sigma^2} \right) + \frac{\exp(-2cM_n) - \exp(-2cp_n)}{\exp(2c) - 1},$$

which verifies that $R_n(w^*_{n,N}) \sim R_n(w^*_n)$ under Conditions M2 and A2, and accords with the second conclusion of Theorem 4 and the third conclusion of Theorem 6.

(iii) When $M_n \geq m^*_n$ for any sufficiently large $n$, we have

$$\frac{1}{n} R_n(w^*_{n,N}) \sim \frac{1}{n} R_n(w^*_n) \sim \frac{1}{2c} \frac{\sigma^2}{n} \log \left( \frac{n}{\sigma^2} \right).$$

which also verifies that $R_n(w^*_{n,N}) \sim R_n(w^*_n)$ under Conditions M2 and A2, and accords with the second conclusion of Theorem 4 and the third conclusion of Theorem 6.

Figure 2: Numerical illustration for Example 5.1 with $\alpha = 0.8$. Left: plots of $\lim_{n \to \infty} \frac{R_n(w^*_{n,N})}{R_n(w^*_n)}$ against $N \in \{1, \ldots, 10\}$ for $\kappa = 0.5, 1, 2$, respectively. Right: plots of $\lim_{n \to \infty} \frac{R_n(w^*_{n,dN})}{R_n(w^*_{n,d})}$ against $\kappa \in (0, 8)$ for $N = 1, 2, 4$, respectively.
6 Simulation Studies

In this section, we conduct several simulation studies to verify the theoretical results presented in Corollaries [1 and 3], where the specific MS and MA methods are compared. Here we choose AIC, BIC, and LOO-CV as MS methods, and MMA and JMA for MA methods. Specifically, we use the following three examples:

- **Example 1**: General nested framework (i.e., \( \nu_m \neq m \)), homoscedastic and uncorrelated errors, and (approximately) orthonormal design;

- **Example 2**: Typical nested framework (i.e., \( \nu_m = m \)), heteroscedastic and autocorrelated errors, and (approximately) orthonormal design;

- **Example 3**: Typical nested framework (i.e., \( \nu_m = m \)), homoscedastic and uncorrelated errors, and non-orthonormal design.

To evaluate the estimators, we compute the risks of the competing methods by computing averages across 1000 replications. Supplementary materials contain more simulation studies.

**Example 1 (General nested framework)** We use the same set-up as that of Peng and Yang (2021) except the coefficients \( \beta_m \)'s. Specifically, suppose the data come from the model (2.1), where \( p_n = \lfloor 5n^{2/3} \rfloor \), \( x_{i1} = 1 \), the remaining \( x_{ij} \) are independent and identically distributed (iid) from \( \mathcal{N}(0, 1) \), and the random errors \( \varepsilon_i \) are iid from \( \mathcal{N}(0, \sigma^2) \) and are independent of \( x_{ij} \)'s. The population \( R^2 \) is denoted by \( R^2 = \frac{\text{var}(\mu_i)}{\text{var}(y_i)} \), which is controlled in 0.25, 0.5 or 0.75 via the parameter \( \sigma^2 \). We consider a more general nested model setting than that of Peng and Yang (2021) by setting

\[
\nu_m = \begin{cases} 
5\lfloor m/2 \rfloor + 2, & \text{if } m \text{ is odd} \\
5\lfloor m/2 \rfloor, & \text{if } m \text{ is even}
\end{cases}, \quad m = 1, \ldots, q_n - 1
\]

and \( \nu_{q_n} = p_n \). Thus, the size of the \( m \)th group of predictors is 2 when \( m \) is odd and 3 when \( m \) is even, \( m = 1, \ldots, q_n - 1 \). We consider two cases with different coefficient decaying orders:
• Case 1. \( \beta_j = m^{-\alpha_1} \) when \( x_{ij} \) is in the \( m \)th group and \( \alpha_1 \) is set to be 1, 1.5 or 2.

• Case 2. \( \beta_j = \exp(-\alpha_2 m) \) when \( x_{ij} \) is in the \( m \)th group and \( \alpha_2 \) is set to be 1, 1.5 or 2.

For Case 1, we know that \( \theta_{n,m} \) converges to \( \theta_m^* = m^{-2\alpha_1}/\sigma^2 \) in probability and then Condition B1 is satisfied (in our theories, we take the predictors as fixed, but in simulation, they are random. When verifying our conditions, we do not consider this randomness), and for Case 2, \( \theta_{n,m} \) converges to \( \theta_m^* = \exp(-2\alpha_2 m)/\sigma^2 \) in probability and then Condition B2 is satisfied.

The sample size \( n \) varies at 50, 500, 1000, 2000, 3000, and 4000. The number of candidate models is determined by \( M_n = \text{INT}(3n^{1/3}) \), where the function \( \text{INT}(a) \) returns the nearest integer from \( a \). In each simulation setting of the combination of \( n \), \( R^2 \), and \( \alpha_1 \) (or \( \alpha_2 \)), we normalize the risks of the MS methods by dividing by the risk of MMA.

Simulation results are summarized in Figures 3–4. In each figure, the simulation results with three different coefficient decaying orders are displayed in rows (a), (b), and (c), respectively. Note that Figure 3 are under Case 1 (slowly decaying coefficients) and Figure 4 are under Case 2 (fast decaying coefficients). Since both AIC and LOO-CV are asymptotically optimal for Example 1, as expected, their performances are very close for large sample size. In the slowly decaying \( \theta_m^* \) case, the performance gap between AIC (or LOO-CV) and MMA does not vanish when \( n \) increases, while in the fast decaying \( \theta_m^* \) case, it becomes very small when \( n \) is large, which are consistent with the results of Corollary 1.

Following Peng and Yang (2021), we also include BIC in our simulation, although often, BIC is not asymptotically optimal. In Case 1, the advantage of AIC over BIC becomes increasingly larger as \( n \) increases from 50 to 4000, while in Case 2 with fast decaying \( \theta_m^* \), BIC is competitive with AIC in some scenarios. This phenomenon was also observed by Peng and Yang (2021).

Example 2 (Heteroscedastic and autocorrelated errors) The setting of this example is the same as that of Example 1 except that the typical nested framework with \( \nu_m = m \) and heteroscedastic and autocorrelated errors are considered. We utilize the same error process of Zhang et al. (2013) that is both heteroscedastic and autocorrelated. Specifically,
the error process is given by \( \varepsilon_i = \varepsilon_{i1} + \varepsilon_{i2} \); \( \varepsilon_{i1} \)'s are independent observations from the \( N(0, \sigma_i^2) \) distribution, and \( \varepsilon_{i2} \) follows an AR(1) process with an autocorrelation coefficient \( \rho_1 = 0.5 \), where \( \varepsilon_{i2} = \rho_1 \varepsilon_{i-1,2} + e_i \), \( \varepsilon_{i2} \sim N(0,1) \), and \( e_i \)'s are iid from \( N(0,1 - \rho_1^2) \) and are independent of \( \varepsilon_{i2} \)'s. Then, the covariance matrix of \( \varepsilon \) given \( x_{ij} \)'s is \( \Omega = \Omega_1 + \Omega_2 \), where

\[
\Omega_1 = \text{diag}\{\sigma_{12}^2, \ldots, \sigma_{n2}^2\} \quad \text{and} \quad \Omega_2 = (\rho_{l-1}^{k-l})_{k,l=1,\ldots,n}.
\]

By a simple calculation, we have

\[
\text{tr}(P_m \Omega_1) \xrightarrow{p} \begin{cases} 1, & \nu_m = 1, \\ \nu_m + 2, & \nu_m \geq 2 \end{cases}, \quad \text{tr}(P_m \Omega_2) \xrightarrow{p} \frac{2\rho_1}{1 - \rho_1} + \nu_m.
\]

Therefore, for any fixed \( m \), \( \theta_{n,m} \to \theta_m^* = \beta_m^2/\zeta_m \) in probability, where

\[
\zeta_m = \begin{cases} \frac{2}{1 - \rho_1}, & m = 1, \\ 4, & m = 2, \\ 2, & m \geq 3. \end{cases}
\]

We consider two cases with different decaying orders of \( \theta_m^* \):

- **Case 1 (With \( \theta_m^* \) satisfying Condition B1).** Here, \( \beta_m = c\sqrt{\zeta_m}m^{-\alpha_1} \) and \( \alpha_1 \) is set to be 1, 1.5 or 2.

- **Case 2 (With \( \theta_m^* \) satisfying Condition B2).** Here, \( \beta_m = c\sqrt{\zeta_m}\exp(-\alpha_2 m) \) and \( \alpha_2 \) is set to be 1, 1.5 or 2.

As Hansen and Racine (2012), the parameter \( c \) was selected to control the approximate population \( \tilde{R}^2 = c^2/(1 + c^2) \) to vary on 0.25, 0.5, and 0.75. The sample size is varied among \( n = 500, 1000, 2000, 3000, 4000, \) and 5000. To verify the results in Corollary 3 we include JMA without the restriction \( \sum_{m=1}^{M_n} w_m = 1 \), denoted by JMA2 as a competing method. In each simulation setting of combination of \( n, \tilde{R}^2 \), and \( \alpha_1 \) (or \( \alpha_2 \)), we normalize the risks of the MS methods and JMA2 by dividing by the risk of JMA.

Simulation results are shown in Figures 5–6. In each figure, the simulation results with three different decaying orders of \( \theta_m^* \) are displayed in rows (a), (b), and (c), respectively. From these results, we see that in the slowly decaying \( \theta_m^* \) case (Figure 5), the performance gap between LOO-CV and JMA does not vanish when sample size increases, while in the
fast decaying $\theta^*_m$ case (Figure 6), it becomes very small when the sample size is large, which are consistent with the results of Corollary 1. Note that from Figure 6, the performances of AIC and JMA are not consistently close since AIC may not be asymptotically optimal in Example 2 because of heteroscedasticity. Another observation is that the performances of JMA2 and JMA are very close when $n$ is sufficiently large, which verify the results in Corollary 3. Moreover, we can observe the same phenomena as that in Example 1 for a comparison of AIC and BIC.

Example 3 (Non-orthonormal design) The setting of this example is the same as that of Example 1 except that the typical nested framework with $\nu_m = m$ and predictors are non-orthonormal. Specifically, the predictors $(x_{i1}, \ldots, x_{ipn})^\top$, $i = 1, \ldots, n$, are iid normal random vectors with zero mean and covariance matrix between $k$th and $l$th elements being $\rho_2^{|k-l|}$, and the random errors $\varepsilon_i$ are iid from $N(0, \sigma^2)$ and are independent of $x_{ij}$’s. Here, $\rho_2$ is set to be 0.5. It is easy to prove that for any fixed $m$,

$$\frac{1}{n} \mu^\top P_m \mu \overset{p}{\to} \lim_{n \to \infty} \beta_{pn}^\top \Sigma_{m \times p_n}^{-1} \Sigma_{m \times m} \beta_{pn},$$

where $\Sigma_{d_1 \times d_2}$ is a $d_1 \times d_2$ matrix with $(k, l)$th element being $\rho_2^{|k-l|}$ and $\beta_{pn} = (\beta_1, \ldots, \beta_{pn})^\top$.

It follows that $\theta_{n,m} = \mu^\top (P_m - P_{m-1}) \mu / (n \sigma^2) \to \theta^*_m = \xi_m / \sigma^2$ in probability, where $\xi_1 = \lim_{n \to \infty} (\Sigma_{1 \times p_n} \beta_{pn})^2$ and

$$\xi_m = \lim_{n \to \infty} \beta_{pn}^\top \left( \Sigma_{m \times p_n} \Sigma_{m \times m} - \Sigma_{(m-1) \times p_n} \Sigma_{(m-1) \times (m-1)} \Sigma_{(m-1) \times p_n} \right) \beta_{pn}$$

for $m = 2, \ldots, p_n$. By some calculations, we can obtain simple forms of $\xi_m$ as follows

$$\xi_1 = \lim_{n \to \infty} \left( \sum_{j=1}^{p_n} \beta_j \rho_2^{j-1} \right)^2, \quad \xi_m = \lim_{n \to \infty} (1 - \rho_2^2) \left( \sum_{j=m}^{p_n} \beta_j \rho_2^{j-m} \right)^2, \quad m \geq 2. \quad (6.1)$$

We consider two cases with different decaying orders of $\theta^*_m$:

- Case 1 (With $\theta^*_m$ satisfying Condition B1). Here, $\xi_m = m^{-2\alpha_1}$ and $\alpha_1$ is set to be 1, 1.5 or 2.

- Case 2 (With $\theta^*_m$ satisfying Condition B2). Here, $\xi_m = \exp(-2\alpha_2 m)$ and $\alpha_2$ is set to be 1, 1.5 or 2.
We can set different coefficient $\beta_j$ via (6.1) such that Case 1 and Case 2 hold respectively. Without loss of generality, we assume $\beta_j \geq 0$ for all $j$. Then from (6.1), we have

$$
\beta_1 = \sqrt{\xi_1 - \rho_2^2} \sqrt{\frac{\xi_2}{1 - \rho_2^2}} \quad \text{and} \quad \beta_j = \frac{\sqrt{\xi_j - \rho_2^2 \sqrt{\xi_{j+1}}}}{\sqrt{1 - \rho_2^2}}, \quad j \geq 2.
$$

The sample size $n$ varies at 50, 500, 1000, 2000, 3000, and 4000. In each simulation setting of the combination of $n$, $R^2$, and $\alpha_1$ (or $\alpha_2$), we normalize the risks of the MS methods by dividing by the risk of MMA. Figures 7–8 display the simulation results for Case 1 and Case 2, respectively. In each figure, the simulation results with three different decaying orders of $\theta_m^*$ are displayed in rows (a), (b), and (c), respectively. From these results, we can see the same observations as that in Example 1, which also verify the previous theoretical findings.

In above examples, we use the decaying orders of GVI to determine the performance of MAs and MSs and set large enough $M_n$, i.e., (Condition M2 is satisfied). In Section of the Supplementary Material, we further design Example 4 to verify Corollary [1] when $M_n$ is too small (Condition M1 is satisfied).

7 Conclusion

This paper extends the work of Peng and Yang (2021) on comparison of MS and MA to a general model setting, where we allow the predictors are non-orthonormal, the error terms are heteroscedastic and autocorrelated, and some predictors are totally unimportant. We obtain the results that the number of candidate models $M_n$ and the decaying order of $\{\theta_{n,m}\}_{m=1}^{dn}$ determine when MA is better than MS. Specifically, when $M_n$ is large enough and $\theta_{n,m}$ decays slowly in $m$, the benefit of MA over MS is real; when $M_n$ is too small or $M_n$ is large enough and $\theta_{n,m}$ decays fast in $m$, the risks of MA and MS are asymptotically equivalent. Furthermore, the obtained results are extended to compare MAs with the weights belonged to three different weight sets.

Along with the paper, there are a few open questions. First, an interesting issue is how to order the predictors and prepare nested candidate models such that the risk gain of MA is optimal. Although various procedures are proposed to order the predictors in
the implementation of MA such as forward selection approach (Claeskens et al., 2006), the marginal correlation (Ando and Li, 2014, 2017; Zhang et al., 2016b), and solution path algorithm of penalized regression (Feng and Liu, 2020; Zhang et al., 2020), there is still a lack of theoretical study on an optimal way of ordering the predictors. Second, it is interesting to develop a data-driven way to choose the number of the candidate models. Another appealing direction is to compare MS and MA in the non-nested model setting. However, in this case, it is difficult to characterize the unknown optimal model $m^*_n$ and weights $w^*_n$. A deeper and detailed investigation of these issues warrants further studies.

**Appendix**

A.1 Proof of Theorem 1

The risk of the $m$th candidate model is

$$R_n(m) = E\|\hat{\mu}_m - \mu\|^2$$

$$= \text{tr} \{E \{(\hat{\mu}_m - \mu)(\hat{\mu}_m - \mu)^\top\}\}$$

$$= \text{tr} \{(E\hat{\mu}_m - \mu)(E\hat{\mu}_m - \mu)^\top\} + \text{tr} \{\text{var}(\hat{\mu}_m)\}$$

$$= \mu^\top(I_n - P_m)\mu + \text{tr} (P_m\Omega).$$

Observe that

$$R_n(m) - R_n(m-1) = \text{tr}\{(P_m - P_{m-1})\Omega\} - \mu^\top(P_m - P_{m-1})\mu = n\text{tr}\{(P_m - P_{m-1})\Omega\}\left(\frac{1}{n} - \theta_{n,m}\right),$$

(A.1)

where $\theta_{n,m}$ is defined in (3.2). Note that $\text{tr}\{(P_m - P_{m-1})\Omega\} > 0$ and $\{\theta_{n,m}\}_{m=1}^n$ is non-increasing from Assumption 3. Then, under Assumption 6, it is easy to see that the global optimal model $m^*_n$ that minimizes $R_n(m)$ on $\{1, \ldots, d_n\}$ satisfies

$$\theta_{n,m^*_n} > \frac{1}{n} \geq \theta_{n,m^*_n+1}.$$  

(A.2)

Hence, the risk of the optimal model $m^*_n$ is

$$R_n(m^*_n) = \mu^\top(I_n - P_{m^*_n})\mu + \text{tr}(P_{m^*_n}\Omega),$$

(A.3)
where when \( M_n < m_n^{**}, m_n^* = M_n \) and \( \theta_{n,m_n^*} > 1/n \); when \( M_n \geq m_n^{**}, m_n^* = m_n^{**} \) and

\[
\theta_{n,m_n^*} > \frac{1}{n} \geq \theta_{n,m_n^*+1}. \tag{A.4}
\]

The risk of the MA estimator with weights \( w \) is

\[
R_n(w) = E\|\hat{\mu}(w) - \mu\|^2 = E\|P(w)y - \mu\|^2 \\
= \mu^\top \{P(w) - I_n\}^2 \mu + \text{tr}\{P^2(w)\Omega\}. 
\]

Rewrite \( P(w) = \sum_{m=1}^{M_n} \gamma_m (P_m - P_{m-1}) \), where \( \gamma_m = \sum_{j=m}^{M_n} w_j \) and \( P_0 = 0 \). Since \( P_mP_t = P_{\text{min}(m,t)} \) for the nested candidate models, it is easy to verify that \( \{P_m - P_{m-1}\}_{m=1}^{M_n} \) are mutually orthonormal projection matrices, i.e.,

\[
(P_{m_1} - P_{m_1-1})(P_{m_2} - P_{m_2-1}) = \begin{cases} P_{m_1} - P_{m_1-1}, & \text{if } m_1 = m_2, \\ 0, & \text{if } m_1 \neq m_2. \end{cases}
\]

Using the above fact, \( R_m(w) \) is further expanded as

\[
R_n(w) = \sum_{m=1}^{M_n} \left( \gamma_m^2 \left[ \mu^\top (P_m - P_{m-1}) \mu + \text{tr}\{(P_m - P_{m-1})\Omega\} \right] \\
- 2\gamma_m \mu^\top (P_m - P_{m-1}) \mu + \mu^\top (P_m - P_{m-1}) \mu \right) + \mu^\top (I_n - P_{M_n}) \mu. \tag{A.5}
\]

It is straightforward to show that the infeasible optimal weight \( w_n^* = (w_{n,1}^*, \ldots, w_{n,M_n}^*)^\top \) can be obtained by setting \( w_{n,m}^* = \gamma_{n,m}^* - \gamma_{n,m+1}^* \) for \( m = 1, \ldots, M_n - 1 \) and \( w_{n,M_n}^* = \gamma_{n,M_n}^* \), where \( \gamma_{n,1}^* = 1 \) and

\[
\gamma_{n,m}^* = \frac{\mu^\top (P_m - P_{m-1}) \mu}{\mu^\top (P_m - P_{m-1}) \mu + \text{tr}\{(P_m - P_{m-1})\Omega\}} = \frac{\theta_{n,m}}{\theta_{n,m} + 1/n}, \quad m = 2, \ldots, M_n. \tag{A.6}
\]

Hence, the risk of the optimal MA estimator is

\[
R_n(w_n^*) = \text{tr}(P_1\Omega) + \sum_{m=2}^{M_n} \frac{\text{tr}\{(P_m - P_{m-1})\Omega\} \mu^\top (P_m - P_{m-1}) \mu}{\mu^\top (P_m - P_{m-1}) \mu + \text{tr}\{(P_m - P_{m-1})\Omega\}} + \mu^\top (I_n - P_{M_n}) \mu. \tag{A.7}
\]

Combining (A.3) and (A.7), the potential advantage of MA over MS is

\[
\Delta_n = R_n(m_n^*) - R_n(w_n^*)
\]
Therefore, we have
\[
R_n \left( \begin{array}{c} P_m - P_{m-1} \end{array} \right)^{\top} \mu \left( P_m - P_{m-1} \right) \mu + \mu^{\top} \left( P_m - P_{m-1} \right) \mu + \mu^{\top} \left( I_n - P_{m_n} \right) \mu
\]

which implies that, as is expected, the optimal risk of MA is not larger than that of MS, i.e.,
\[
R_n(w_n^*) \leq R_n(m_n^*). \quad \text{We consider two scenarios that } M_n < m_n^{**} \text{ and } M_n \geq m_n^{**}. \]

When \( M_n < m_n^{**} \), \( m_n^* = M_n \) and it follows from Assumption 3 and \( \theta_n,m_n^* > 1/n \) that \( \{\gamma_{n,m}^*\}_{m=1}^{M_n} \) is non-increasing and \( \gamma_{n,m_n^*} > 1/2 \). Then, for a sufficiently large \( n \),
\[
R_n(w_n^*) \geq \sum_{m=1}^{m_n^*} \frac{\mu^{\top} (P_m - P_{m-1}) \mu + \mu^{\top} (I_n - P_{m_n^*}) \mu}{2} + \frac{1}{2} R_n(m_n^*).
\]

When \( M_n \geq m_n^{**} \), it follows from Assumption 3 and (A.4) that \( \gamma_{n,m_n^*} > 1/2 \geq \gamma_{n,m_{n+1}^*} \). Then, for a sufficiently large \( n \),
\[
R_n(w_n^*) \geq \sum_{m=1}^{M_n} \frac{\mu^{\top} (P_m - P_{m-1}) \mu + \mu^{\top} (I_n - P_{M_n}) \mu}{2} + \frac{1}{2} R_n(m_n^*).
\]

Therefore, we have \( R_n(m_n^*) \geq R_n(w_n^*) \geq R_n(m_n^*)/2 \) for any sufficiently large \( n \), which yields that \( R_n(m_n^*) \) and \( R_n(w_n^*) \) have the same order. This completes the proof of Theorem.
A.2 Proof of Theorem 2

We first prove (i). Let $C > 0$ be a given sufficiently large constant. From Assumption 5, there exists a constant $K^*_C = \max\{K_m, [2/\bar{\theta}_n(C)+1] + 1\} > 0$ such that $\theta_n, C = K^*_C = \max\{K_m, [2/\bar{\theta}_n(C)+1] + 1\} > 0$ for any $n \geq K^*_C$. Since $m^*_n$ satisfies $1/n = \theta_n, C = K^*_C > 0$ from (A.2), we have

$$\theta_n, C = \theta_n, m^*_n + 1 \geq \theta_n, C = K^*_C > 0$$

which, along with Assumption 3, leads to $m^*_n + 1 \geq [C] + 2$. This implies that for any constant $C > 0$, there exists a constant $K^*_C > 0$ such that $m^*_n \geq [C] + 1 > C$ for any $n \geq K^*_C$, i.e., $\lim_{n \to \infty} m^*_n = \infty$. This completes the proof of Theorem 2(i).

Next, we prove (ii). When $M_n \geq m^*_n$, $m^*_n = m^*_n$ and thus

$$R_n(m^*_n) \geq \text{tr}(P_m^*\Omega) = \text{tr}(P_m^*\Omega) \geq c_1 \nu_m^* \geq c_1 m^*_n \to \infty.$$  

When $M_n < m^*_n$, $m^*_n = M_n$ and thus by (A.2) and Assumptions 2–3,

$$R_n(m^*_n) = R_n(M_n) = \mu^\top (I_n - P_{M_n}) \mu + \text{tr}(P_{M_n}\Omega)
\geq \mu^\top (P_m^* - P_{M_n}) \mu + \text{tr}(P_{M_n}\Omega)
= \sum_{m=M_n+1}^{m^*_n} \text{tr}\{(P_m - P_{m-1})\Omega\} n\theta_n, m + \text{tr}(P_{M_n}\Omega)
\geq n\theta_n, m^*_n \sum_{m=M_n+1}^{m^*_n} \text{tr}\{(P_m - P_{m-1})\Omega\} + \text{tr}(P_{M_n}\Omega)
= \text{tr}(P_{m^*_n}\Omega) \geq c_1 \nu_m^* \geq c_1 m^*_n \to \infty.$$  (A.9)

Therefore, $R_n(m^*_n) \to \infty$ as $n \to \infty$ for any $M_n$. Combining it with Theorem 1, we have $R_n(w^*_n) \geq \frac{1}{2} R_n(m^*_n) \to \infty$ as $n \to \infty$. This completes the proof of Theorem 2(ii).

A.3 Proof of Theorem 3

Under Condition M1, $\lim_{n \to \infty} M_n / m^*_n = 0$, which implies that $M_n < m^*_n$ when $n$ is large enough and thus $m^*_n = M_n$. By (A.8), for a sufficiently large $n$,

$$\Delta_n = \sum_{m=2}^{M_n} \mu^\top (P_m - P_{m-1}) \mu + \text{tr}\{(P_m - P_{m-1})\Omega\} \geq \frac{1}{2} R_n(m^*_n) \to \infty$$

31
\[ \leq \sum_{m=2}^{M_n} \text{tr}\{(P_m - P_{m-1})\Omega\} \]
\[ = \text{tr}\{(P_{M_n} - P_1)\Omega\} \]
\[ \leq c_2(n_{M_n} - n_1) \leq c_2V(M_n - 1), \quad (A.10) \]

where the last two inequalities are due to Assumptions 2 and 4, respectively. Combining (A.9), (A.10), \( \lim_{n \to \infty} M_n/m_n^{**} = 0 \), and Theorem 2 we have
\[ \lim_{n \to \infty} \frac{\Delta_n}{R_n(m_n^{*})} \leq \frac{c_2}{c_1} \lim_{n \to \infty} \frac{M_n - 1}{m_n^{**}} = 0, \]
which yields that \( \Delta_n = o\{R_n(m_n^{*})\} \). This completes the proof of Theorem 3.

### A.4 Proof of Theorem 4

When Condition M2 holds, we consider two scenarios: \( M_n \geq m_n^{**} \) and \( \zeta \leq M_n/m_n^{**} < 1 \) for any sufficiently large \( n \), to prove this theorem.

(i) \( M_n \geq m_n^{**} \) for any sufficiently large \( n \). In this case, \( m_n^{*} = m_n^{**} \) satisfies (A.4). When Condition A1 holds, we first examine the order of the optimal risk of MS. Let \( s_n^{*} = \max\{s : \lfloor k^*(m_n^{*}) + 1 \rfloor \leq d_n, s = 0, 1, \ldots\} \). The first term in (A.3) is upper bounded by

\[
\mu^\top (I_n - P_{m_n^{**}})\mu \\
= \sum_{m=m_n^{**}+1}^{q_n} \mu^\top (P_m - P_{m-1})\mu = \sum_{m=m_n^{**}+1}^{d_n} \mu^\top (P_m - P_{m-1})\mu \\
= \sum_{s=0}^{s_n^{**} - 1} \sum_{m=[k^*(m_n^{*}) + 1]}^{[k^*(m_n^{*})+1] - 1} \mu^\top (P_m - P_{m-1})\mu + \sum_{m=[k^*(m_n^{*}) + 1]}^{d_n} \mu^\top (P_m - P_{m-1})\mu \\
= \sum_{s=0}^{s_n^{**} - 1} \sum_{m=[k^*(m_n^{*}) + 1]}^{[k^*(m_n^{*})+1] - 1} \text{ntr}\{(P_m - P_{m-1})\Omega\} \theta_{n,m} + \sum_{m=[k^*(m_n^{*}) + 1]}^{d_n} \text{ntr}\{(P_m - P_{m-1})\Omega\} \theta_{n,m} \\
\leq \sum_{s=0}^{s_n^{**} - 1} \theta_{n,[k^*(m_n^{*}) + 1]} \sum_{m=[k^*(m_n^{*}) + 1]}^{[k^*(m_n^{*})+1] - 1} \text{ntr}\{(P_m - P_{m-1})\Omega\} \\
+ \theta_{n,[k^*(m_n^{*}) + 1]} \sum_{m=[k^*(m_n^{*}) + 1]}^{d_n} \text{ntr}\{(P_m - P_{m-1})\Omega\} \\
\leq n \theta_{n,m_n^{*}+1} \sum_{s=0}^{s_n^{**} - 1} \eta^s \text{tr}\{(P_{[k^*(m_n^{*})+1]} - P_{[k^*(m_n^{*})+1]-1})\Omega\}.
\]
The first term in (A.8) can be lower bounded by

\[ + n\theta_{n,m_n^*+1} \eta^s \text{tr}\{(P_{d_n} - P_{k^*(m_n^*+1) - 1}) \Omega\} \]

\[ \leq c_2 \sum_{s=0}^{s_n^* - 1} \eta^s (\nu_{k^*(m_n^*+1) - 1} - \nu_{k^*(m_n^*+1) - 1}) + c_2 \eta^s \nu_{d_n - \nu_{k^*(m_n^*+1) - 1}} \]

\[ \leq c_2 V \sum_{s=0}^{s_n^*} \eta^s ([k^+1(m_n^* + 1)] - [k^*(m_n^* + 1)]) \]

\[ \sim c_2 V (k - 1)(m_n^* + 1) \sum_{s=0}^{s_n^*} (k\eta)^s \leq m_n^* \leq \text{tr}(P_{m_n^*} \Omega), \]

where the first equality follows from the fact that \( \mu^\top(I_n - P_{q_n})\mu = 0 \), the first inequality follows from Assumption 3, the second inequality follows from \( \theta_{n,[k^*(m_n^* + 1)]}/\theta_{n,m_n^*+1} \leq \eta^s \) for a sufficiently large \( n \), which can be obtained by Condition A1 and Theorem 2 and Peng and Yang (2021) that \( \lim_{t \to \infty} R_n \Theta_{m_n^*} \leq \text{optimal risk of MS satisfies} \]

\( R_n(m_n^*) = \text{tr}(P_{m_n^*} \Omega). \)

Next, we prove that the potential advantage \( \Delta_n \) of MA over MS has the same order as \( R_n(m_n^*) \) under Condition A1. Define \( t_n = \min\{t \in \mathbb{N} : [kt] \geq m_n^* + 1\} \). Then it follows from Theorem 2 and Peng and Yang (2021) that \( \lim_{n \to \infty} t_n = \infty, [kt_n] \sim m_n^*, \) and \( t_n \sim m_n^*/k \).

The first term in (A.8) can be lower bounded by

\[ \sum_{m=2}^{m_n^*} \text{tr}\{(P_m - P_{m-1}) \Omega\} - \frac{\text{tr}\{(P_m - P_{m-1}) \Omega\} \mu^\top(P_m - P_{m-1}) \mu}{\mu^\top(P_m - P_{m-1}) \mu + \text{tr}\{(P_m - P_{m-1}) \Omega\}} \]

\[ \geq \text{tr}\{(P_{m_n^*} - P_1) \Omega\} - \sum_{m=2}^{[kt_n]} \frac{\text{tr}\{(P_m - P_{m-1}) \Omega\} \mu^\top(P_m - P_{m-1}) \mu}{\mu^\top(P_m - P_{m-1}) \mu + \text{tr}\{(P_m - P_{m-1}) \Omega\}} \]

\[ \geq \text{tr}\{(P_{m_n^*} - P_{t_n}) \Omega\} - \sum_{m=2}^{t_n} \text{tr}\{(P_m - P_{m-1}) \Omega\} - \sum_{m=t_n+1}^{[kt_n]} \frac{\text{tr}\{(P_m - P_{m-1}) \Omega\}}{1 + 1/(n\theta_{n,m})} \]

\[ \geq \text{tr}\{(P_{m_n^*} - P_{t_n}) \Omega\} - \frac{1}{1 + 1/(n\theta_{n,t_n})} \text{tr}\{(P_{[kt_n]} - P_{t_n}) \Omega\}, \]

\[ \geq \text{tr}\{(P_{m_n^*} - P_{t_n}) \Omega\} - \frac{1}{1 + \delta} \text{tr}\{(P_{[kt_n]} - P_{t_n}) \Omega\} \]

\[ = \frac{1}{1 + \delta} \text{tr}\{(1 + \delta)P_{m_n^*} - P_{[kt_n]} - \delta P_{t_n} \Omega\} \tag{A.11} \]

where the third inequality follows from Assumption 3 and the last inequality follows from the following fact

\[ \frac{1}{1 + 1/(n\theta_{n,t_n})} \leq \frac{1}{1 + \delta/(n\theta_{n,[kt_n]})} \leq \frac{1}{1 + \delta/(n\theta_{n,m_n^*+1})} \leq \frac{1}{1 + \delta}. \]
which can be derived by (A.4) and Condition A1. Since $\nu_{m*}^n \sim \nu_{[ktn]}$, it is easy to show that 
$$(1 + \delta)P_{m*}^n - P_{[ktn]} - \delta P_{tn}$$
is positive semi-definite for sufficiently large $n$. By Assumption 2 and the fact that $\text{tr}(AB) \geq \lambda_{\text{min}}(A)\text{tr}(B)$ for symmetric matrix $A$ and positive semi-definite matrix $B$ (Bernstein, 2005, Proposition 8.4.13), we have

$$
\frac{1}{1 + \delta} \text{tr}\left[\{(1 + \delta)P_{m*}^n - P_{[ktn]} - \delta P_{tn}\} \Omega\right] \\
\geq \frac{c_1}{1 + \delta} \left\{ (1 + \delta)\nu_{m*}^n - \nu_{[ktn]} - \delta \nu_{tn} \right\} \\
\geq \frac{c_1}{1 + \delta} (\nu_{m*}^n - \nu_{[ktn]}) + \frac{c_1 \delta}{1 + \delta} (m^*_n - t_n) \\
\sim \frac{(k - 1)c_1 \delta}{k(1 + \delta)} m^*_n \preceq \text{tr}(P_{m*}^n \Omega),
$$
where the last line is due to $\nu_{m*}^n \sim \nu_{[ktn]}$ and $t_n \sim m^*_n/k$. From (A.8), we see

$$R_n(m^*_n) \geq \Delta_n \geq \frac{m^*_n}{2} \left[ \text{tr}\left\{(P_m - P_{m-1})\Omega\right\} - \frac{\text{tr}\left\{(P_m - P_{m-1})\Omega\right\} \mu^\top (P_m - P_{m-1}) \mu}{\mu^\top (P_m - P_{m-1}) \mu + \text{tr}\left\{(P_m - P_{m-1})\Omega\right\}} \right].$$

which, along with (A.11) and (A.12), implies $\Delta_n \approx R_n(m^*_n)$. This completes the proof of the result under Condition A1.

When Condition A2 holds, we next examine $\Delta_n = o\{R_n(m^*_n)\}$. Let $2/m^*_n < k' < 1$. The first term in (A.8) is upper bounded by

$$
\sum_{m=2}^{m^*_n} \left[ \text{tr}\left\{(P_m - P_{m-1})\Omega\right\} - \frac{\text{tr}\left\{(P_m - P_{m-1})\Omega\right\} \mu^\top (P_m - P_{m-1}) \mu}{\mu^\top (P_m - P_{m-1}) \mu + \text{tr}\left\{(P_m - P_{m-1})\Omega\right\}} \right] \\
\leq \text{tr}\{(P_{m*}^n - P_1)\Omega\} - \frac{1}{1 + 1/(n\theta_{m*}^n)} \sum_{m=2}^{k' m^*_n} \text{tr}\{(P_m - P_{m-1})\Omega\} \\
\leq \text{tr}\{(P_{m*}^n - P_1)\Omega\} - \frac{1}{1 + 1/(n\theta_{m*}^n, k' m^*_n)} \sum_{m=2}^{k' m^*_n} \text{tr}\{(P_m - P_{m-1})\Omega\} \\
= \text{tr}\{(P_{m*}^n - P_1)\Omega\} - \frac{1}{1 + 1/(n\theta_{m*}^n, k' m^*_n)} \text{tr}\{(P_{[k' m^*_n]} - P_1)\Omega\} \\
= \text{tr}\left\{ \left( P_{m*}^n - P_1 - \frac{P_{[k' m^*_n]} - P_1}{1 + 1/(n\theta_{m*}^n, k' m^*_n)}) \right) \Omega \right\}. \quad (A.13)
$$

Observe that

$$P_{m*}^n - P_1 - \frac{P_{[k' m^*_n]} - P_1}{1 + 1/(n\theta_{m*}^n, k' m^*_n)}) = \frac{P_{m*}^n - P_{[k' m^*_n]} + (P_{m*}^n - P_1)/(n\theta_{m*}^n, k' m^*_n)}{1 + 1/(n\theta_{m*}^n, k' m^*_n)})$$
is a positive semi-definite matrix. By the fact that \(\text{tr}(AB) \leq \lambda_{\max}(A)\text{tr}(B)\) for symmetric matrix \(A\) and positive semi-definite matrix \(B\) (Bernstein 2005, Proposition 8.4.13), we have

\[
\text{tr}\left\{ \left( P_{m_n^*} - P_1 - \frac{P_{k'm_n^*} - P_1}{1 + 1/(n\theta_{n,[k'm_n^*]})} \right) \Omega \right\} \\
\leq \frac{c_2}{1 + 1/(n\theta_{n,[k'm_n^*]})} \left( \text{tr}(P_{m_n^*} - P_{k'm_n^*}) + \frac{P_{m_n^*} - P_1}{n\theta_{n,[k'm_n^*]}} \right) \\
= \frac{c_2}{1 + 1/(n\theta_{n,[k'm_n^*]})} \left( \nu_{m_n^*} - \nu_{k'm_n^*} + \frac{\nu_{m_n^*} - \nu_1}{n\theta_{n,[k'm_n^*]}} \right) \\
\leq \frac{c_2}{1 + 1/(n\theta_{n,[k'm_n^*]})} \left( m_n^* - [k'm_n^*] + \frac{m_n^* - 1}{n\theta_{n,[k'm_n^*]}} \right) \\
\leq c_2 V \left\{ m_n^* - [k'm_n^*] + \frac{\theta_{n,m_n^*}}{\theta_{n,[k'm_n^*]}} (m_n^* - 1) \right\},
\]

(A.14)

where the second inequality follows from Assumption 4. Since \(\lim_{n \to \infty} \theta_{n,m_n^*}/\theta_{n,[k'm_n^*]} = 0\) for any \(k' < 1\) under Condition A2 and Theorem 2, we have

\[
\left\{ m_n^* - [k'm_n^*] + \frac{\theta_{n,m_n^*}}{\theta_{n,[k'm_n^*]}} (m_n^* - 1) \right\} / m_n^* = 1 - \frac{[k'm_n^*]}{m_n^*} + \frac{\theta_{n,m_n^*}}{\theta_{n,[k'm_n^*]}} \left( 1 - \frac{1}{m_n^*} \right) \to 1 - k',
\]

which, along with (A.13) and (A.14), yields that

\[
\sum_{m=2}^{m_n^*} \left[ \text{tr}\{(P_m - P_{m-1})\Omega\} - \frac{\text{tr}\{(P_m - P_{m-1})\Omega\} \mu^\top(P_m - P_{m-1})\mu}{\mu^\top(P_m - P_{m-1})\mu + \text{tr}\{(P_m - P_{m-1})\Omega\}} \right] = O\{(1 - k')m_n^*\}.
\]

Due to the arbitrariness of \(k'\) and the fact \(\text{tr}(P_{m_n^*}\Omega) \asymp m_n^*\), letting \(k' \to 1\), we can obtain the first term of (A.8):

\[
\sum_{m=2}^{m_n^*} \left[ \text{tr}\{(P_m - P_{m-1})\Omega\} - \frac{\text{tr}\{(P_m - P_{m-1})\Omega\} \mu^\top(P_m - P_{m-1})\mu}{\mu^\top(P_m - P_{m-1})\mu + \text{tr}\{(P_m - P_{m-1})\Omega\}} \right] = o\{\text{tr}(P_{m_n^*}\Omega)\}.
\]

(A.15)

Next, we consider the order of the second term of (A.8). Choose \(k > 1\). We have

\[
\sum_{m=m_n^*+1}^{M_n} \frac{\{\mu^\top(P_m - P_{m-1})\mu\}^2}{\mu^\top(P_m - P_{m-1})\mu + \text{tr}\{(P_m - P_{m-1})\Omega\}} = \sum_{m=m_n^*+1}^{[k(m_n^*+1)+1]} \frac{n\theta_{n,m}}{1 + 1/(n\theta_{n,m})} \text{tr}\{(P_m - P_{m-1})\Omega\} + \sum_{m=[k(m_n^*+1)+1]}^{\min\{M_n,d_n\}} \frac{\mu^\top(P_m - P_{m-1})\mu}{1 + 1/(n\theta_{n,m})}.
\]

(A.16)
The first term of (A.16) is upper bounded by

\[
\sum_{m=\lfloor k(m_n^*+1) \rfloor}^{k(m_n^*+1)} \frac{n\theta_{n,m}}{1+1/(n\theta_{n,m})} \text{tr}\{(P_m - P_{m-1})\Omega\} \\
\leq \frac{n\theta_{n,m_n^*+1}}{1+1/(n\theta_{n,m_n^*+1})} \sum_{m=\lfloor k(m_n^*+1) \rfloor}^{k(m_n^*+1)} \text{tr}\{(P_m - P_{m-1})\Omega\} \\
\leq \frac{1}{2} \text{tr}\{(P_{\lfloor k(m_n^*+1) \rfloor} - P_{m_n^*})\Omega\} \\
\leq \frac{c_2}{2} (\nu_{\lfloor k(m_n^*+1) \rfloor} - \nu_{m_n^*}) \\
\leq \frac{c_2}{2} V(|k(m_n^*+1)| - m_n^*),
\]

where the first two inequalities follow from Assumption 3 and (A.4), respectively, and the last inequality follows from Assumption 4. Using Theorem 2 as \( n \to \infty \),

\[
\frac{|k(m_n^*+1)| - m_n^*}{m_n^*} = \frac{|k(m_n^*+1)|}{m_n^*} - 1 \to k - 1.
\]

Therefore,

\[
\sum_{m=\lfloor k(m_n^*+1) \rfloor}^{k(m_n^*+1)} \frac{n\theta_{n,m}}{1+1/(n\theta_{n,m})} \text{tr}\{(P_m - P_{m-1})\Omega\} = O\{(k-1)m_n^*\} = O\{(k-1)\text{tr}(P_m; \Omega)\}. \quad (A.17)
\]

The second term of (A.16) can be upper bounded by

\[
\sum_{m=\lfloor k(m_n^*+1) \rfloor+1}^{\min\{M_n,d_n\}} \frac{\mu^\top (P_m - P_{m-1}) \mu}{1+1/(n\theta_{n,m})} \\
\leq \frac{1}{1+1/(n\theta_{n,[k(m_n^*+1)]})} \sum_{m=\lfloor k(m_n^*+1) \rfloor+1}^{\min\{M_n,d_n\}} \mu^\top (P_m - P_{m-1}) \mu \\
\leq \frac{1}{1 + \theta_{n,m_n^*+1}/\theta_{n,[k(m_n^*+1)]}} \mu^\top (P_{\min\{M_n,d_n\}} - P_{\lfloor k(m_n^*+1) \rfloor}) \mu \\
\leq \frac{1}{1 + \theta_{n,m_n^*+1}/\theta_{n,[k(m_n^*+1)]}} \mu^\top (I_n - P_{m_n^*}) \mu \\
= o\{\mu^\top (I_n - P_{m_n^*}) \mu\}, \quad (A.18)
\]

where the first two inequalities follow from Assumption 3 and (A.4), respectively, the last inequality follows from the following fact

\[
\mu^\top (I_n - P_{m_n^*}) \mu = \mu^\top (I_n - P_{\min\{M_n,d_n\}}) \mu + \mu^\top (P_{\min\{M_n,d_n\}} - P_{\lfloor k(m_n^*+1) \rfloor}) \mu
\]

36
\[ + \mu^\top (P_{[k(m_n^*+1)]} - P_{m_n^*}) \mu \]
\[ \geq \mu^\top (P_{\min\{M_n,d_n\}} - P_{[k(m_n^*+1)]}) \mu. \]

and the last equality follows from the fact that \( \lim_{n \to \infty} \theta_{n,\lceil k(m_n^*+1) \rceil}/\theta_{n,m_n^*+1} = 0 \) for any \( k > 1 \) under Condition A2. Combining (A.16), (A.17), and (A.18), we have
\[
\sum_{m=m_n^*+1}^{M_n} \frac{\{\mu^\top (P_m - P_{m-1}) \mu\}^2}{\mu^\top (P_m - P_{m-1}) \mu + \text{tr}\{(P_m - P_{m-1})\Omega\}} = O\{(k-1)\text{tr}(P_{m_n^*} \Omega) + o(\mu^\top (I_n - P_{m_n^*}) \mu)\}.
\]

Due to the arbitrariness of \( k \), letting \( k \to 1 \), we have
\[
\sum_{m=m_n^*+1}^{M_n} \frac{\{\mu^\top (P_m - P_{m-1}) \mu\}^2}{\mu^\top (P_m - P_{m-1}) \mu + \text{tr}\{(P_m - P_{m-1})\Omega\}} = o\{R_n(m_n^*)\},
\]
which, along with (A.8) and (A.15), leads to \( \Delta_n = o\{R_n(m_n^*)\}. \) This completes the proof of the result under Condition A2.

(ii) \( 0 < M_n/m_n^* < 1 \) for any sufficiently large \( n \). In this case, \( m_n^* = M_n \approx m_n^* \). When Condition A1 holds, there exists a finite positive integer \( \tau_1 \) such that \( k^{-\tau_1} \leq \xi \). Therefore,
\[
\theta_{n,m_n^*+1} = \theta_{n,M_n+1} \leq \theta_{n,\lceil m_n^* \rceil+1} \leq \theta_{n,\lceil k^{-\tau_1}(m_n^*)+1 \rceil} \leq \delta^{-\tau_1} \theta_{n,m_n^*+1} \leq \delta^{-\tau_1} \frac{1}{n},
\]
(A.19)

where the last inequality is due to (A.2). Then, using the same arguments in (i) and (A.19), it is easy to prove the result under Condition A1. When Condition A2 holds, we can also obtain (A.15), which, along with the fact that the second term of (A.8) equals 0, yields the result under Condition A2. This completes the proof of Theorem 4 under (ii).

### A.5 Proof of Lemma 1

From Assumption 7, we know that for any small \( 0 < \epsilon < 1 \), there exists a constant \( K_\epsilon > 0 \) which does not depend on \( m \), such that \( 0 < 1 - \epsilon \leq \theta_{n,m}/\theta_m^* \leq 1 + \epsilon \) holds uniformly in \( m = 1, \ldots, d_n \) and \( n \geq K_\epsilon \).

(i) When Condition B1 holds, there exist constants \( k > 1 \) and \( 0 < \delta^* \leq \eta^* < 1 \) with \( k\eta^* < 1 \) such that for a sufficiently large \( n \),
\[
\frac{1 - \epsilon}{1 + \epsilon} \delta^* \leq \frac{\theta_{n,\lceil kl_n \rceil}}{\theta_{n,l_n}} = \frac{\theta_{n,\lceil kl_n \rceil}}{\theta_{l_n}^*} \times \frac{\theta_{l_n}^*}{\theta_{l_n}^*} \times \frac{\theta_{l_n}^*}{\theta_{l_n}^*} \leq 1 + \epsilon \eta^*.
\]
Let $\delta = \frac{1-\epsilon}{1+\epsilon} \delta^*$ and $\eta = \frac{1+\epsilon}{1-\epsilon} \eta^*$. Since $\lim_{\epsilon \to 0} \frac{1+\epsilon}{1-\epsilon} = 1$, we can choose a small enough $\epsilon > 0$ such that $0 < \delta \leq \eta < 1$ and $k\eta < 1$. Therefore, Condition B1 implies Condition A1.

(ii) When Condition B2 holds, for every constant $k > 1$ and every integer sequence $\{l_n\}$ satisfied $\lim_{n \to \infty} l_n = \infty$,

$$\lim_{n \to \infty} \frac{\theta_n[\bar{k}l_n]}{\theta_{n,l_n}} = \lim_{n \to \infty} \left\{ \frac{\theta_n[\bar{k}l_n]}{\theta^*[\bar{k}l_n]} \times \frac{\theta^*[\bar{k}l_n]}{\theta_{n,l_n}} \times \frac{\theta_{l_n}}{\theta_{n,l_n}} \right\} \leq \frac{1+\epsilon}{1-\epsilon} \lim_{n \to \infty} \frac{\theta^*[\bar{k}l_n]}{\theta_{l_n}} = 0.$$ 

Therefore, Condition B2 implies Condition A2.

### A.6 Proof of Corollary 1

From Theorem 1, $\frac{1}{2} \leq R_n(w^*_n)/R_n(m^*_n) \leq 1$ for any sufficiently large $n$. Since $R_n(\hat{m})/R_n(m^*_n) = 1 + o_p(1)$ and $R_n(\hat{w})/R_n(w^*_n) = 1 + o_p(1)$, then when $n$ is large enough,

$$\frac{1}{2} \{1 + o_p(1)\} \leq \frac{R_n(\hat{w})}{R_n(\hat{m})} = \frac{R_n(\hat{w})}{R_n(w^*_n)} \frac{R_n(w^*_n)}{R_n(m^*_n)} \frac{R_n(m^*_n)}{R_n(\hat{m})} \leq 1 + o_p(1),$$

which yields that $R_n(\hat{w}) \sim_p R_n(\hat{m})$. Observe that

$$\frac{R_n(\hat{m}) - R_n(\hat{w})}{R_n(\hat{m})} = 1 - \frac{R_n(\hat{w})}{R_n(w^*_n)} \frac{R_n(w^*_n)}{R_n(m^*_n)} \frac{R_n(m^*_n)}{R_n(\hat{m})} + \frac{R_n(\hat{w})}{R_n(w^*_n)} \frac{\Delta_n}{R_n(m^*_n)} \frac{R_n(m^*_n)}{R_n(\hat{m})}.$$  

Under Conditions M2 and A1, from Theorem 4, $\Delta_n/R_n(m^*_n) \geq c^*$ for some $c^* \in (0, 1/2]$ and any sufficiently large $n$. Therefore, when $n$ is large enough,

$$1 \geq \left| \frac{R_n(\hat{m}) - R_n(\hat{w})}{R_n(\hat{m})} \right| \geq \frac{R_n(\hat{w})}{R_n(w^*_n)} \frac{\Delta_n}{R_n(m^*_n)} \frac{R_n(m^*_n)}{R_n(\hat{m})} - \left| 1 - \frac{R_n(\hat{w})}{R_n(w^*_n)} \frac{R_n(m^*_n)}{R_n(\hat{m})} \right| \geq c^* \{1 + o_p(1)\} - o_p(1) = c^* \{1 + o_p(1)\},$$

which leads to $R_n(\hat{m}) - R_n(\hat{w}) \sim_p R_n(\hat{m})$. Under Condition M1 or Conditions M2 and A2, $\lim_{n \to \infty} \Delta_n/R_n(m^*_n) = 0$ from Theorems 3 and 4. Therefore, by (A.20), we have

$$\frac{R_n(\hat{m}) - R_n(\hat{w})}{R_n(\hat{m})} \mathop{\to}^{p} 0,$$

which implies that $R_n(\hat{m}) - R_n(\hat{w}) = o_p(R_n(\hat{m}))$ or $R_n(\hat{m}) \sim_p R_n(\hat{w})$. This completes the proof of Corollary 1.
A.7 Proof of Theorem 5

From (A.5) and Assumption 3, it is easy to see that the risk of the optimal MA estimator without the total weight constraint is

\[ R_n(\tilde{w}_n^*) = \sum_{m=1}^{M_n} \frac{\text{tr}\{P_m - P_{m-1}\} \mu^\top (P_m - P_{m-1})\mu}{\mu^\top (P_m - P_{m-1})\mu + \text{tr}\{P_m - P_{m-1}\} \Omega} + \mu^\top (I_n - P_{M_n})\mu, \]

which, along with (A.7) and Assumption 2, yields that

\[ R_n(w_n^*) - R_n(\tilde{w}_n^*) = \frac{\{\text{tr}(P_1 \Omega)\}^2}{\mu^\top P_1 \mu + \text{tr}(P_1 \Omega)} \leq \text{tr}(P_1 \Omega) < c_2 \nu_1. \]

Furthermore, if Assumptions 4–6 hold, we have \( R_n(w_n^*) \to \infty \) from Theorem 2(ii). Therefore,

\[ R_n(w_n^*) - R_n(\tilde{w}_n^*) = o\{R_n(w_n^*)\}, \]

which completes the proof of Theorem 5.

A.8 Two Lemmas and Their Proofs

Before giving the proof of Theorems 6, we need some lemmas. Let \( \lceil a \rceil \) denote the least integer greater than or equal to \( a \). We first present the following lemma on an expression of \( R_n(w_n^{*N}) \).

**Lemma A.1.** Suppose that Assumptions 3 and 6 hold. For any sufficiently large \( n \), the optimal risk of MA restricted to \( W_n(N) \) is

\[ R_n(w_n^{*N}) = \text{tr}(P_1 \Omega) + \mu^\top (I_n - P_{M_n})\mu \]

\[ + \sum_{i=i_n,N+1}^{N} \sum_{m=m_n(\frac{2i+1}{2N})+1}^{m_n(\frac{2i+1}{2N})+1} \left[ \left( \frac{i}{N} \right)^2 \text{tr}\{(P_m - P_{m-1}) \Omega\} + \left( 1 - \frac{i}{N} \right)^2 \mu^\top (P_m - P_{m-1})\mu \right] \]

\[ + \sum_{m=m_n(\frac{2i_n,N+1}{2N})+1}^{m_n(\frac{2i_n,N+1}{2N})+1} \left[ \left( \frac{i_n,N}{N} \right)^2 \text{tr}\{(P_m - P_{m-1}) \Omega\} + \left( 1 - \frac{i_n,N}{N} \right)^2 \mu^\top (P_m - P_{m-1})\mu \right], \]

where \( i_n,N = \left\lfloor N\gamma_n^{*N} - \frac{1}{2} \right\rfloor \) and \( m_n(z) \) for \( z \in (\gamma_n^{*N}, 1) \) is an integer in \( \{1, \ldots, m_n\} \) satisfying

\[ \theta_{n,m_n(z)} > \frac{z}{(1-z)n} \geq \theta_{n,m_n(z)+1}, \quad (A.21) \]

and \( m_n(z_0) = 1 \) for any \( z_0 \geq 1 \).
Proof. Since $w \in W_n(N)$, we have $\gamma_m = \sum_{j=m}^{M_n} w_{j} \in \{0, 1/N, 2/N, \ldots, 1\}$. Observe that

$$f_m(\gamma_m) \equiv \gamma_m^2 \left[ \mu^\top (P_m - P_{m-1}) \mu + \text{tr}((P_m - P_{m-1}) \Omega) \right] - 2\gamma_m \mu^\top (P_m - P_{m-1}) \mu + \mu^\top (P_m - P_{m-1}) \mu$$

$$= \left[ \mu^\top (P_m - P_{m-1}) \mu + \text{tr}((P_m - P_{m-1}) \Omega) \right] (\gamma_m - \gamma_{n,m}^*)^2 + \gamma_{n,m}^* \text{tr}((P_m - P_{m-1}) \Omega),$$

where $\gamma_{n,m}^*$ is defined in (A.6). Since $\{\gamma_{n,m}^*\}_{m=1}^{M_n}$ is non-increasing, it is easy to see that

$$\min_{\gamma_m \in \{0, 1/N, 2/N, \ldots, 1\}} f_m(\gamma_m) = f_m \left( \frac{i}{N} \right), \quad \text{when } \frac{2i - 1}{2N} < \gamma_{n,m}^* \leq \frac{2i + 1}{2N}, \quad i = 0, \ldots, N.$$

Therefore, from (A.5), we have

$$R_n(w_{n,N}^*) = \text{tr}(P_1 \Omega) + \min_{m=2}^{M_n} \sum_{\gamma_m \in \{0, 1/N, 2/N, \ldots, 1\}} f_m(\gamma_m) + \mu^\top (I_n - P_{M_n}) \mu$$

$$= \text{tr}(P_1 \Omega) + \sum_{m=2}^{M_n} \sum_{i=0}^{N} f_m \left( \frac{i}{N} \right) 1 \left\{ \frac{2i - 1}{2N} < \gamma_{n,m}^* \leq \frac{2i + 1}{2N} \right\} + \mu^\top (I_n - P_{M_n}) \mu$$

$$= \text{tr}(P_1 \Omega) + \sum_{m=2}^{M_n} \sum_{i=0}^{N} \left[ \left( \frac{i}{N} \right)^2 \text{tr}((P_m - P_{m-1}) \Omega) + \left( 1 - \frac{i}{N} \right)^2 \mu^\top (P_m - P_{m-1}) \mu \right]$$

$$\times 1 \left\{ \frac{2i - 1}{2N} < \gamma_{n,m}^* \leq \frac{2i + 1}{2N} \right\} + \mu^\top (I_n - P_{M_n}) \mu,$$

where $1\{\cdot\}$ denotes the usual indicator function. By the definition of $m_n(z)$ in (A.21), we have $\frac{2i - 1}{2N} < \gamma_{n,m}^* \leq \frac{2i + 1}{2N}$ if and only if $m_n\left(\frac{2i+1}{2N}\right) + 1 \leq m \leq m_n\left(\frac{2i-1}{2N}\right)$ for $i = i_{n,N} + 1, \ldots, N$ and $\frac{2i_{n,N} - 1}{2N} < \gamma_{n,m}^* \leq \frac{2i_{n,N} + 1}{2N}$ if and only if $m_n\left(\frac{2i_{n,N}+1}{2N}\right) + 1 \leq m \leq M_n$, where

$$i_{n,N} = \min \left\{ i = 0, 1, \ldots, N : \gamma_{n,M_n}^* \leq \frac{2i + 1}{2N} \right\} = \left[ N\gamma_{n,M_n}^* - \frac{1}{2} \right].$$

Combining the above fact with (A.22), it is easy to obtain the expression of $R_n(w_{n,N}^*)$ in Lemma A.1. Moreover, we can obtain another expression of $R_n(w_{n,N}^*)$ as follows:

$$R_n(w_{n,N}^*) = R_n(w_{n}^*) + \sum_{m=2}^{M_n} \left[ \mu^\top (P_m - P_{m-1}) \mu + \text{tr}((P_m - P_{m-1}) \Omega) \right]$$

$$\times \sum_{i=0}^{N} \left( \frac{i}{N} - \gamma_{n,m}^* \right)^2 1 \left\{ \frac{2i - 1}{2N} < \gamma_{n,m}^* \leq \frac{2i + 1}{2N} \right\}.$$  \hspace{1cm} (A.23)

This completes the proof of Lemma A.1. \hfill \Box

Note that $m_n(1/2) = m_n^{**}$. Next, we present some elementary properties of $m_n(z)$ in the following lemma.
Lemma A.2. Suppose that Assumptions 3 and 5 hold. Then, \( m_n(z) \) for \( z \in (\gamma^*_n, 1) \) defined in Lemma A.1 satisfies the following properties.

(i) \( m_n(z) \) is a non-increasing function in \( z \); \( \lim_{n \to \infty} m_n(z) = \infty \) for any fixed \( z \in (\gamma^*_n, 1) \).

(ii) If there exist constants \( k > 1, \eta < 1, \) and \( K > 1 \) such that \( \theta_{n,[k]} / \theta_{n,l} \leq \eta \) for any \( n \geq K \) and any integer sequence \( \{l_n\} \) satisfies \( \lim_{n \to \infty} l_n = \infty \), then \( m_n(z_1) > m_n(z_2) \) for any \( \gamma^*_n < z_1 \neq z_2 < 1 \).

Proof. The results of (i) are easily shown by Assumption 1 and the similar arguments in the proof of Lemma 2. Next, we shall prove (ii). Without loss of generality, we assume \( z_1 < z_2 \), which follows that \( m_n(z_1) \geq m_n(z_2) \). Observe there exists an integer \( s > 0 \) such that \( \frac{z_2}{1-z_1} \geq \frac{z_1}{1-z_2} \eta^s \). Then, by the definition of \( m_n(\xi) \), we have

\[
\theta_{n,m_n(z_1)} > \frac{z_1}{(1-z_1)n} \geq \frac{z_2}{(1-z_2)n} \eta^s \geq \eta^s m_n(z_2) + 1 \geq \theta_{n,[k^*(m_n(z_2) + 1)]}.
\]

(A.24)

Thus, \( m_n(z_1) < \lfloor k^*(m_n(z_2) + 1) \rfloor \), which, along with \( m_n(z_1) \geq m_n(z_2) \), yields that \( m_n(z_1) > m_n(z_2) \). This completes the proof of Lemma A.2. \(\square\)

A.9 Proof of Theorem 6

Observe that

\[
\mu^\top (P_m - P_{m-1}) \mu + \text{tr}((P_m - P_{m-1})\Omega) = \frac{\mu^\top (P_m - P_{m-1}) \mu}{\gamma^*_{n,m}} = \frac{\text{tr}((P_m - P_{m-1})\Omega)}{1 - \gamma^*_{n,m}}, \quad (A.25)
\]

which, along with (A.23), yields that

\[
R_n(w^*_n) - R_n(w^*_n) = \sum_{m=2}^{m_n} \text{tr}((P_m - P_{m-1})\Omega) \sum_{i=0}^{N} \frac{\left( \frac{i}{N} - \gamma^*_{n,m} \right)^2}{1 - \gamma^*_{n,m}} \left\{ \frac{2i-1}{2N} < \gamma^*_{n,m} \leq \frac{2i+1}{2N} \right\}
\]

\[
+ \sum_{m=m_n+1}^{M_n} \mu^\top (P_m - P_{m-1}) \mu \sum_{i=0}^{N} \gamma^*_{n,m} \left\{ \frac{2i-1}{2N} < \gamma^*_{n,m} \leq \frac{2i+1}{2N} \right\}
\]

\[
\leq \frac{1}{2N} \sum_{m=2}^{m_n} \text{tr}((P_m - P_{m-1})\Omega) + \frac{1}{2N} \sum_{m=m_n+1}^{M_n} \mu^\top (P_m - P_{m-1}) \mu
\]

41
\[ \sum_{m=2}^{m^*_n} \text{tr}\{(P_m - P_{m-1})\Omega\}(1 - \gamma^*_{m,m})1\{\gamma^*_{m,m} > 1 - 1/(2N)\} \]

\[ = \sum_{m=2}^{m^*_n(2N-1)/2N} \text{tr}\{(P_m - P_{m-1})\Omega\} - \sum_{m=2}^{m^*_n(2N-1)/2N} \frac{\text{tr}\{(P_m - P_{m-1})\Omega\}}{1 + 1/(n\theta_{n,m})} \]

\[ \geq \text{tr}\{(P_{m_n(2N-1)/2N} - P_{t^N_n})\Omega\} - \frac{1}{1 + 1/(n\theta_{n,t^N_n})} \text{tr}\{(P_{[kt^N_n]} - P_{t^N_n})\Omega\} \]

\[ \geq \frac{c_1}{1 + \frac{\delta}{2N-1}} \left\{ \left(1 + \frac{\delta}{2N-1}\right) \nu _{m_n(2N-1)/2N} - \nu _{[kt^N_n]} - \frac{\delta}{2N-1} P_{t^N_n} \right\} \Omega \]

\[ \geq \frac{c_1}{1 + \frac{\delta}{2N-1}} (\nu _{m_n(2N-1)/2N} - \nu _{[kt^N_n]}) + \frac{c_1\delta}{2N-1 + \delta} \left\{ m_n \left(\frac{2N-1}{2N}\right) - t^N_n \right\} \]

\[ \sim \frac{c_1(k-1)\delta}{k(2N-1 + \delta)} m_n^* \left(\frac{2N-1}{2N}\right) \approx m^*_n, \] \hspace{1cm} (A.26)

where the second inequality is derived by the fact

\[ \frac{1}{1 + 1/(n\theta_{n,t^N_n})} \leq \frac{1}{1 + \delta/(n\theta_{n,[kt^N_n]})} \leq \frac{1}{1 + \delta/(n\theta_{n,m_n(2N-1)/2N} + 1)} \leq \frac{1}{1 + \delta/(2N-1)}, \]
and the last line is due to \(\nu_{m_n(\frac{2N-1}{2N})} \sim \nu_{\frac{kM}{h^N}}, t_n \sim m_n(\frac{2N-1}{2N})/k\), and Lemma [A, 2(ii)]. Since

\[
\frac{1}{2N} R_n(m^*_n) \geq R_n(w^*_n, N) - R_n(w^*_n) \geq \sum_{m=2}^{m^*_n} \text{tr}\{(P_m - P_{m-1})\Omega\} \left(1 - \gamma^*_m\right) 1\{\gamma^*_m > 1 - 1/(2N)\},
\]

using (A.26) and \(\text{tr}(P_m \Omega) \approx R_n(m^*_m) \approx R_n(w^*_n)\), we have \(R_n(w^*_n, N) - R_n(w^*_n) \approx R_n(w^*_n)\).

Next, consider \(M_n < m_n(\frac{2N-1}{2N})\) but \(m_n/m^*_n \geq \epsilon\). Using (A.19) and the similar arguments in (A.26), we can also prove \(R_n(w^*_n, N) - R_n(w^*_n) = o\{R_n(w^*_n)\}\) is directly followed by Theorems [3 4] and the fact \(R_n(m^*_n) \geq R_n(w^*_n, N) \geq R_n(w^*_n)\).

### A.10 Proof of the Results in Examples 6.1–6.2

Using the expression of \(R_n(w^*_n, N)\) in Lemma [A, 1] we have that for any sufficiently large \(n\),

\[
\frac{1}{n} R_n(w^*_n, N) = \frac{\sigma^2}{n} + \sum_{i=1, N+1}^{N} \sum_{m=m_n(\frac{2i+1}{2N})+1}^{m^*_n} \left\{\frac{\sigma^2}{n} \left(\frac{i}{N}\right)^2 + \left(1 - \frac{i}{N}\right)^2 \beta^2_m\right\}
\]

\[
+ \sum_{m=m_n(\frac{2i+1}{2N})+1}^{M_n} \left\{\frac{\sigma^2}{n} \left(\frac{i_n, N}{N}\right)^2 + \left(1 - \frac{i_n, N}{N}\right)^2 \beta^2_m\right\} + \sum_{m=M_n+1}^{p_n} \beta^2_m.
\]

**Proof of the results in Example 6.1:** When \(\beta_m = m^{-\alpha}\) for \(\alpha > 1/2\), we have \(m_n(\frac{2i+1}{2N}) \sim (\frac{2N}{2i+1} - 1)^{-\frac{\alpha}{2}} (\frac{n}{\sigma^2})^{\frac{1}{2\alpha}}\) for \(i = i_n, N, \ldots, N - 1\) and \(m^*_n \sim (\frac{n}{\sigma^2})^{\frac{1}{2\alpha}}\). When \(M_n = M\) is fixed as \(n \to \infty\), \(i_n, N = N\) for any sufficiently large \(n\). Therefore,

\[
\frac{1}{n} R_n(w^*_n, N) = \frac{M\sigma^2}{n} + \sum_{m=M+1}^{p_n} m^{-2\alpha} \sim \sum_{m=M+1}^{\infty} m^{-2\alpha}.
\]

When \(M_n \to \infty\) as \(n \to \infty\), the optimal risk of MA restricted to \(W_n(N)\) satisfies

\[
\frac{1}{n} R_n(w^*_n, N) \sim \frac{\sigma^2}{n} + \sum_{i=1}^{N} \int_{m_n(\frac{2i+1}{2N})}^{m^*_n} \left\{\frac{\sigma^2}{n} \left(\frac{i}{N}\right)^2 + \left(1 - \frac{i}{N}\right)^2 x^{-2\alpha}\right\} dx
\]

\[
+ \int_{m_n(\frac{2i+1}{2N})}^{M_n} \left\{\frac{\sigma^2}{n} \left(\frac{i_n, N}{N}\right)^2 + \left(1 - \frac{i_n, N}{N}\right)^2 x^{-2\alpha}\right\} dx + \int_{M_n}^{p_n} x^{-2\alpha} dx
\]

\[
\equiv \frac{\sigma^2}{n} + \Pi_n + \Pi_n + \frac{1}{2\alpha - 1} (M_n^{-2\alpha} - p_n^{-2\alpha+1}). \quad (A.27)
\]
Since $m_{n}^{**} \sim (\frac{n}{\sigma^2})^{\frac{1}{2\alpha}}$, it is easy to see that $i_{n, N} \sim i_{n, N}^{*} \equiv \left[ \frac{N}{1 + (\frac{N}{m_{n}^{*}})^{2\alpha}} - \frac{1}{2} \right]$. We first simplify $\Pi_{n1}$ as follows:

\[
\Pi_{n1} = \frac{\sigma^2}{n} \sum_{i = i_{n, N} + 1}^{N} \left( \frac{i}{N} \right)^2 \left\{ m_n \left( \frac{2i - 1}{2N} \right) - m_n \left( \frac{2i + 1}{2N} \right) \right\} 
- \frac{1}{2\alpha - 1} \sum_{i = i_{n, N} + 1}^{N} \left( 1 - \frac{i}{N} \right)^2 \left\{ m_n \left( \frac{2i - 1}{2N} \right)^{1-2\alpha} - m_n \left( \frac{2i + 1}{2N} \right)^{1-2\alpha} \right\} 
= \frac{\sigma^2}{n} \frac{2}{N} \sum_{i = i_{n, N}}^{N-1} \frac{2(2i + 1)}{2N} m_n \left( \frac{2i + 1}{2N} \right) + \frac{1}{2\alpha - 1} \sum_{i = i_{n, N}}^{N-1} \left( 1 - \frac{2i + 1}{2N} \right) m_n \left( \frac{2i + 1}{2N} \right)^{1-2\alpha} 
- \frac{\sigma^2}{n} \frac{2}{\sigma^2} \left( \frac{i_{n, N}}{N} \right)^{\frac{1}{2\alpha - 1}} \frac{2}{N} \sum_{i = i_{n, N}}^{N-1} \left( \frac{2i + 1}{2N} \right)^{1-\frac{1}{2\alpha}} \left( 1 - \frac{2i + 1}{2N} \right) - \frac{\sigma^2}{n} \left( \frac{i_{n, N}}{N} \right)^2 m_n \left( \frac{2i_{n, N} + 1}{2N} \right)^{1-2\alpha}. \tag{A.28}
\]

Next, we simplify $\Pi_{n2}$ as follows:

\[
\Pi_{n2} = \frac{\sigma^2}{n} \left( \frac{i_{n, N}}{N} \right)^2 \left\{ M_n - m_n \left( \frac{2i_{n, N} + 1}{2N} \right) \right\} 
- \frac{1}{2\alpha - 1} \left( 1 - \frac{i_{n, N}}{N} \right)^2 \left\{ M_n^{1-2\alpha} - m_n \left( \frac{2i_{n, N} + 1}{2N} \right)^{1-2\alpha} \right\} 
\sim \left( \frac{n}{\sigma^2} \right)^{\frac{1}{2\alpha - 1}} \left( \frac{i_{n, N}}{N} \right)^{\frac{1}{2\alpha - 1}} m_n \left( \frac{m_{n}^{**}}{m_n} \right) + \frac{1}{2\alpha - 1} \left( 1 - \frac{i_{n, N}}{N} \right)^2 m_n \left( \frac{2i_{n, N} + 1}{2N} \right)^{1-2\alpha}. \tag{A.29}
\]

Combining (A.27), (A.28), and (A.29), we have that when $M_n \to \infty$ as $n \to \infty$,

\[
\frac{1}{n} R_n(w_{n}^{*}) \sim \frac{2\alpha}{2\alpha - 1} \left( \frac{n}{\sigma^2} \right)^{\frac{1}{2\alpha - 1}} \psi_{n, N} + \frac{1}{2\alpha - 1} \left( M_n^{-2\alpha + 1} - p_n^{-2\alpha + 1} \right), \tag{A.30}
\]

where

\[
\psi_{n, N} = \frac{2}{N} \sum_{i = i_{n, N}}^{N-1} \left( \frac{2i + 1}{2N} \right)^{1-\frac{1}{2\alpha}} \left( 1 - \frac{2i + 1}{2N} \right)^{\frac{1}{2\alpha}} \frac{2\alpha - 1}{2\alpha} \left( \frac{i_{n, N}}{N} \right)^2 \frac{M_n}{m_{n}^{**}} - \frac{1}{2\alpha} \left( 1 - \frac{i_{n, N}}{N} \right)^2 \left( \frac{M_n}{m_{n}^{**}} \right)^{1-2\alpha}.
\]

When $M_n \to \infty$ as $n \to \infty$, it is shown in Peng and Yang (2021) that the optimal risk
of MA with the weight set \( \mathcal{W}_n \) satisfies

\[
\frac{1}{n} R_n(w_n^*) \sim \frac{1}{2\alpha} \left( \frac{n}{\sigma^2} \right)^{\frac{1}{2\alpha} - 1} \left\{ \frac{\pi}{\sin\left(\frac{\pi}{2\alpha}\right)} - B\left(\frac{1}{1 + \left(\frac{M_n}{m_n}\right)^{2\alpha}} ; 1 - \frac{1}{2\alpha}, \frac{1}{2\alpha}\right) \right\} + \frac{1}{2\alpha - 1} (M_n^{2\alpha+1} - p_n^{2\alpha+1}).
\]

(A.31)

When \( M_n \equiv M \) is fixed as \( n \to \infty \),

\[
\frac{1}{n} R_n(w_{n,N}^*) = \frac{\sigma^2}{n} + \frac{M}{n} \frac{1}{\sigma^2 + m^{2\alpha}} + \frac{p_n}{m^{2\alpha}} \sim \frac{1}{m^{2\alpha}} \sim \sum_{m=M+1}^{\infty} m^{-2\alpha}.
\]

Therefore, we consider different conditions on \( M_n \) as follows.

(i) When \( M_n \equiv M \) is fixed as \( n \to \infty \),

\[
\frac{1}{n} R_n(w_{n,N}^*) \sim \frac{1}{n} R_n(w_n^*) \sim \sum_{m=M+1}^{\infty} m^{-2\alpha}.
\]

(ii) When \( M_n \to \infty \) but \( M_n/m_n^* \to 0 \) as \( n \to \infty \), \( i_n^* = N \) for any sufficiently large \( n \) and thus \( \psi_{n,N} = o(1) \), which, along with the fact that \( B(1; 1 - \frac{1}{2\alpha}, \frac{1}{2\alpha}) = \frac{\pi}{\sin\left(\frac{\pi}{2\alpha}\right)} \), yields that

\[
\frac{1}{n} R_n(w_{n,N}^*) \sim \frac{1}{n} R_n(w_n^*) \sim \frac{1}{2\alpha - 1} (M_n^{2\alpha+1} - p_n^{2\alpha+1}) \sim \frac{M_n^{2\alpha+1}}{2\alpha - 1}.
\]

(iii) When \( M_n/m_n^* \geq \zeta \) for some \( \zeta > 0 \), let us find the lower bound of \( R_n(w_{n,N}^*) - R_n(w_n^*) \).

If \( M_n \geq m_n \left(\frac{2N-1}{2N}\right) \), note

\[
\sum_{m=2}^{m_n^*} \text{tr}\{(P_m - P_{m-1})\Omega\}(1 - \gamma_{n,m}^*) I\{\gamma_{n,m}^* > 1 - 1/(2N)\}
\]

\[
= \sum_{m=2}^{m_n \left(\frac{2N-1}{2N}\right)} \sigma^2 \left(1 - \frac{\beta_m^2}{\beta_m^2 + \sigma^2/n}\right) \geq \sum_{m=\lceil m_n \left(\frac{2N-1}{2N}\right)\rceil/2}^{m_n \left(\frac{2N-1}{2N}\right)} \frac{\sigma^4/n}{m^{-2\alpha} + \sigma^2/n}
\]

\[
\geq \left[\frac{1}{2} m_n \left(\frac{2N-1}{2N}\right)\right] \frac{\sigma^4/n}{\left[m_n \left(\frac{2N-1}{2N}\right)/2\right]^{-2\alpha} + \sigma^2/n} \sim \frac{(2N - 1)^{-\frac{\pi}{2\alpha} + \sigma^2}}{2^{2\alpha+1}(2N - 1) + 2 \left(\frac{n}{\sigma^2}\right)^{\frac{1}{2\alpha}}}. \]

If \( m_n \left(\frac{2N-1}{2N}\right) > M_n \geq \zeta m_n^* \), we also have

\[
\sum_{m=2}^{m_n^*} \text{tr}\{(P_m - P_{m-1})\Omega\}(1 - \gamma_{n,m}^*) I\{\gamma_{n,m}^* > 1 - 1/(2N)\}
\]

\[
\geq \left[\frac{\zeta m_n^*}{2}\right] \frac{\sigma^4/n}{\left[\zeta m_n^*/2\right]^{-2\alpha} + \sigma^2/n} \sim \frac{\zeta \sigma^2}{2^{2\alpha + 1} \zeta^{-2\alpha} + 2 \left(\frac{n}{\sigma^2}\right)^{\frac{1}{2\alpha}}}. \]
As a result, \( R_n(\mathbf{w}_{n,N}^*) - R_n(\mathbf{w}_n^*) \) can be lower bounded by \( \frac{\varpi \sigma^2}{2^{2\alpha+1} \varpi - 2^{2\alpha+2}} \left( \frac{n}{\sigma^2} \right)^{\frac{1}{2\alpha}} \), where \( \varpi = \min\{\varepsilon, (2N - 1)^{-\frac{1}{2\alpha}} \} \). Moreover, if \( \lim_{n \to \infty} M_n/m_{n}^{**} = \kappa \in (0, \infty] \) and \( M_n = o(p_n) \) are satisfied, it follows from (A.30) and (A.31) that

\[
\lim_{n \to \infty} \frac{R_n(\mathbf{w}_{n,N}^*)}{R_n(\mathbf{w}_n^*)} = \frac{1}{\psi_N^*} \left[ \frac{2\alpha - 1}{4\alpha^2} \left\{ \frac{\pi}{\sin(\frac{\pi}{2\alpha})} - B \left( \frac{1}{1 + \kappa^{2\alpha}}; 1 - \frac{1}{2\alpha}, \frac{1}{2\alpha} \right) \right\} + \frac{\kappa^{-2\alpha+1}}{2\alpha} \right],
\]

where

\[
\psi_N^* = \frac{2}{N} \sum_{i=i_N}^{N-1} \left( \frac{2i + 1}{2N} \right)^{\frac{1}{2\alpha}} \left( 1 - \frac{2i + 1}{2N} \right)^{\frac{1}{2\alpha}} + \frac{2\alpha - 1}{2\alpha} \left( \frac{i_N^*}{N} \right)^2 \kappa - \frac{1}{2\alpha} \left( 1 - \frac{i_N^*}{N} \right)^2 \kappa^{1-2\alpha}
\]

and \( i_N^* = \left\lfloor \frac{N}{1 + \kappa^{2\alpha}} - \frac{1}{2} \right\rfloor \). It is easy to see that \( \left\{ \psi_N^* \right\}_{N=1}^{\infty} \) is a strictly decreasing sequence with \( \psi_1^* = 1 - \frac{\kappa^{-2\alpha+1}}{2\alpha} \). Moreover, we can prove that

\[
\lim_{N \to \infty} \psi_N^* = 2 \int_{1 + \kappa^{2\alpha}}^1 t^{-\frac{1}{2\alpha}} (1 - t)^{\frac{1}{2\alpha}} dt + \frac{2\alpha - 1}{4\alpha^2} \kappa \left( 1 + \kappa^{2\alpha} \right)^2 - \frac{1}{2\alpha} \kappa^{1+2\alpha}
\]

\[
= \frac{2\alpha - 1}{4\alpha^2} \int_{1 + \kappa^{2\alpha}}^1 t^{-\frac{1}{2\alpha}} (1 - t)^{\frac{1}{2\alpha}-1} dt
\]

\[
= \frac{2\alpha - 1}{4\alpha^2} \left\{ \frac{\pi}{\sin(\frac{\pi}{2\alpha})} - B \left( \frac{1}{1 + \kappa^{2\alpha}}; 1 - \frac{1}{2\alpha}, \frac{1}{2\alpha} \right) \right\},
\]

where the last equality follows from the fact that \( B(1; 1 - \frac{1}{2\alpha}, \frac{1}{2\alpha}) = \frac{\pi}{\sin(\frac{\pi}{2\alpha})} \). Therefore, for any fixed \( N \geq 1 \),

\[
\lim_{n \to \infty} \frac{R_n(\mathbf{w}_{n,N}^*)}{R_n(\mathbf{w}_n^*)} < 1.
\]

Proof of the results in Example 6.2: When \( \beta_m = \exp(-cm) \) for \( c > 0 \), we have \( m_n \left( \frac{2c+1}{2N} \right) \sim \frac{1}{2c} \log \left( \frac{n}{\sigma^2} \right) \) for \( i = i_{n,N}, \ldots, N-1 \) and \( m^{**}_n \sim \frac{1}{2c} \log \left( \frac{n}{\sigma^2} \right) \). The optimal risk of MA satisfies

\[
\frac{1}{n} R_n(\mathbf{w}_n^*) = \frac{\sigma^2}{n} + \sum_{m=2}^{M_n} \frac{1}{n} \frac{n}{\sigma^2 + \exp(2cm)} + \sum_{m=M_n+1}^{p_n} \exp(-2cm)
\]

\[
\sim \sum_{m=1}^{M_n} \frac{1}{n} \frac{n}{\sigma^2 + \exp(2cm)} + \frac{\exp(-2cM_n) - \exp(-2cp_n)}{\exp(2c) - 1}. \tag{A.32}
\]

We consider different conditions on \( M_n \) as follows.

(i) When \( \limsup_{n \to \infty} M_n/m_{n}^{**} < 1 \), \( M_n < m_{n}^{**} \) for any sufficiently large \( n \). Thus,

\[
\frac{1}{n} R_n(m_n^*) = \frac{M_n \sigma^2}{n} + \sum_{m=M_n+1}^{p_n} \exp(-2cm) = \frac{M_n \sigma^2}{n} + \frac{\exp(-2cM_n) - \exp(-2cp_n)}{\exp(2c) - 1}. \tag{A.33}
\]
By $2cm_n^* \sim \log \left( \frac{n}{\sigma} \right)$ and $\lim_{n \to \infty} \log(M_n/m^*) = 0$, we observe that

$$\limsup_{n \to \infty} \log \left\{ \frac{M_n \sigma^2/n}{\exp(-2cM_n)} \right\} / (2cm_n^*) = \limsup_{n \to \infty} \log M_n - \log \left( \frac{n}{\sigma^2} \right) + 2cM_n 
\leq -1 + \limsup_{n \to \infty} \frac{M_n}{m^*} < 0,$$

which implies that $\frac{M_n \sigma^2/n}{\exp(-2cM_n)} \to 0$ as $n \to \infty$. Moreover, as $n \to \infty$,

$$\frac{\exp(-2cp_n)}{\exp(-2cM_n)} = \exp\{ -2c(p_n - M_n) \} \leq \exp\{ -2c(m^* - M_n) \} \to 0.$$

Therefore, we have $\frac{1}{n} R_n(m_n^*) \sim \frac{\exp(-2cM_n)}{\exp(2c) - 1}$. Since $\sum_{m=1}^{M_n} \left\{ \frac{n}{\sigma^2} + \exp(2cm) \right\}^{-1} \leq \frac{c^2}{n} M_n$, from (A.32), we have $\frac{1}{n} R_n(w_n^*) \sim \frac{\exp(-2cM_n)}{\exp(2c) - 1}$. Therefore,

$$\frac{1}{n} R_n(m_n^*) \sim \frac{1}{n} R_n(w_n^*) \sim \frac{\exp(-2cM_n)}{\exp(2c) - 1}.$$

(ii) When $M_n \geq m^*$ for any sufficiently large $n$, note that as $n \to \infty$,

$$\frac{\exp(-2cm_n^*)}{m_n^* \sigma^2/n} \leq \frac{\exp(-2cm_n^*)}{m_n^* \exp\{-2c(m_n^* + 1)\}} = \frac{\exp(2c)}{m_n^*} \to 0,$$

where the inequality is due to $\sigma^2/n \geq \exp\{-2c(m_n^* + 1)\}$ derived from (A.2). Therefore, we have

$$\frac{1}{n} R_n(m_n^*) = \frac{m_n^* \sigma^2}{n} + \frac{\exp(-2cm_n^*) - \exp(-2cp_n)}{\exp(2c) - 1} \sim \frac{m_n^* \sigma^2}{n}.$$

Next, we investigate $R_n(w_n^*)$. From (A.32),

$$\frac{1}{n} R_n(w_n^*) \sim \sum_{m=1}^{M_n} \frac{1}{\frac{n}{\sigma^2} + \exp(2cm)} + \sum_{m=M_n+1}^{p_n} \exp(-2cm)$$

$$= \sum_{m=1}^{m_n^*} \frac{1}{\frac{n}{\sigma^2} + \exp(2cm)} + \sum_{m=m_n^*+1}^{M_n} \frac{1}{\frac{n}{\sigma^2} + \exp(2cm)} + \sum_{m=M_n+1}^{p_n} \exp(-2cm)(A.35)$$

For the first term of (A.35), it is easy to obtain

$$\sum_{m=1}^{m_n^*} \frac{1}{\frac{n}{\sigma^2} + \exp(2cm)} \sim \int_0^{m_n^*} \frac{1}{\frac{n}{\sigma^2} + \exp(2cx)} dx$$

$$= \frac{m_n^* \sigma^2}{n} - \frac{1}{2c} \frac{\sigma^2}{n} \log \left\{ 1 + \frac{\sigma^2}{n} \exp(2cm_n^*) \right\} \sim \frac{m_n^* \sigma^2}{n}, \quad (A.36)$$

where the last “~” is due to $\frac{\sigma^2}{n} \exp(2cm_n^*) < 1$ derived from (A.2). For the last two terms of (A.35), using (A.34), we have

$$\sum_{m=m_n^*+1}^{M_n} \frac{1}{\frac{n}{\sigma^2} + \exp(2cm)} + \sum_{m=M_n+1}^{p_n} \exp(-2cm)$$

47
\[
\leq \sum_{m=m_n^{**}+1}^{p_n} \exp(-2cm) = \frac{\exp(-2cm^{**}) - \exp(-2cp_n)}{\exp(2c) - 1} = o\left(\frac{m_n^{**}\sigma^2}{n}\right),
\]
which, along with (A.35) and (A.36), yields that \(\frac{1}{n}R_n(w_n^*) \sim \frac{m_n^{**}\sigma^2}{n}\). Therefore,
\[
\frac{1}{n}R_n(m_n^*) \sim \frac{1}{n}R_n(w_n^*) \sim \frac{m_n^{**}\sigma^2}{n} \sim \frac{1}{2c} \frac{\sigma^2}{n} \log \left(\frac{n}{\sigma^2}\right).
\]

(iii) When \(M_n < m_n^{**}\) for any sufficiently large \(n\) but \(\lim_{n \to \infty} M_n/m_n^{**} = 1\), by using the same arguments in (A.36), we can show that \(\sum_{m=1}^{M_n} \left\{ \frac{n}{\sigma^2} + \exp(2cm) \right\}^{-1} \sim \frac{M_n\sigma^2}{n}\), which, along with (A.32) and (A.33), yields that
\[
\frac{1}{n}R_n(m_n^*) \sim \frac{1}{n}R_n(w_n^*) \sim \frac{1}{2c} \frac{\sigma^2}{n} \log \left(\frac{n}{\sigma^2}\right) + \frac{\exp(-2cM_n) - \exp(-2cp_n)}{\exp(2c) - 1}.
\]

Combining the results of (i)–(iii) and the fact \(R_n(m_n^*) \geq R_n(w_{n,N}^*) \geq R_n(w_n^*)\), we obtain the results of Example 6.2.
