February 28, 2022

Abstract

Chain Event Graphs (CEGs) are a widely applicable class of probabilistic graphical models that are able to represent context-specific independence statements and asymmetric unfoldings of events in an easily interpretable way. Existing model selection literature on CEGs has focused on obtaining the maximum a posteriori (MAP) CEG. However, MAP selection is well-known to ignore model uncertainty. Here, we explore the use of model averaging over this class. We demonstrate that such methods express model uncertainty and lead to more robust inference. Because the space of possible CEGs is huge, scoring models exhaustively for model averaging in all but small problems is prohibitive. However we show that a bespoke class of hybrid forward sampling and greedy search algorithms can successfully and intelligently traverse this space of candidate models. By applying a simple version of our search method to two known case studies, we can illustrate the efficacy of such methods compared to more standard MAP modelling. We also demonstrate how its outputs systematically inform those component hypotheses that are most robustly supported the data and high-scoring alternative models to the MAP model.

1 Introduction

Chain Event Graphs (CEGs) are a class of interpretable graphical models which represent context-specific models on discrete data, including Bayesian Networks (BNs) as a special case. They can provide compact representations of complex independence statements, with each different CEG providing a different explanation of the underlying process. CEGs have been successfully applied in various domains including educational studies [Freeman and Smith, 2011], policing [Bunnin and Smith, 2021], public health [Shenvi and Smith, 2019] and migration studies [Strong et al., 2021].

CEGs are constructed from event trees by setting up a staging on the non-leaf vertices, or the situations, of the tree. Two vertices are defined to be in the same stage when their outgoing edges have the same conditional transition probabilities and share the same real-world meaning. The staging of the tree uniquely defines a staged tree and from the set of staged trees there is a bijection to the set of CEGs [Shenvi and Smith, 2020]. Therefore, for a given probability tree, the model selection depends on deciding between the potential ways of staging a tree.

Other than the ability to represent context-specific independence statements, CEGs differ from BNs by being able to represent domains where processes can unfold in diverse ways. These CEGs are called non-stratified CEGs and examples of their use can be seen in Shenvi and Smith [2019] and Strong et al. [2021]. Learning the context-specific information (the staging of the events) is a non-trivial task with a large
number of possible stagings. The size of the model space of candidate CEGs is given by a product of Bell numbers that grow super-exponentially [Silander and Leong, 2013]. For example, given a stratified CEG with 5 binary variables, there are approximately $1.3 \times 10^{15}$ possible models\(^1\).

Until recently, Bayesian model selection algorithms used to search the spaces of CEGs have been score-based, aiming to maximise the log marginal likelihood, and are of two types: hierarchical agglomerative clustering (HAC) [Freeman and Smith, 2011], a greedy search algorithm; and dynamic programming [Cowell and Smith, 2014], an exhaustive search of the model space which is only possible for small models.

More recently, non-Bayesian approaches to learning the staging structure based on clustering have been used [Carli et al., 2020]. While the score function based on MAP selection is often not appropriate, it does carry the interpretation of being the most probable model \textit{a posteriori}, which is not necessarily true of these other approaches.

The MAP CEG, when used on its own, provides an excellent representation of the underlying data generating process when that candidate has a high posterior probability. However, when this is not the case, focusing only on this model will lead to overconfident and sometimes spurious inferences. This occurs when there are many high-scoring models with non-negligible probabilities: a phenomenon that is common if the size of the model space dwarfs the number of data points, this is a typical scenario in all but the simplest of settings including for CEGs [Tian et al., 2010].

Under this approach, model averaging looks a promising alternative where a set of high scoring models can be used to approximate the complete, more technically sound, Bayesian model average. Examples of such methods include using k-best models [Tian et al., 2010] and Occam’s window [Madigan and Raftery, 1994]. Markov Chain Monte Carlo (MCMC) techniques can also be used for similar purposes [Fragoso et al., 2018].

In the next section, we review the existing literature on model selection of CEGs. Then, we review the literature on model averaging and how this relates to CEGs. In Section 4, we discuss the methodology used in this paper to search a space of CEGs. In Section 5, we present computational results of our methodology and in Section 6 we discuss these results, the limitations and areas for future research in this area.

2 Bayesian learning of CEGs

2.1 Notation and assumptions

In this paper, for simplicity we assume that the probability tree $T$, on which the CEG is based is fixed \textit{a priori}. Any probability tree can be decomposed as a set of florets. Florets are simple sub-trees of depth 1, rooted at the non-leaf vertices, situations, of the tree whose emanating edges can be labelled by the probabilities with which a unit passes to a subsequent vertex of the tree.

A staged tree is a coloured tree that simply partitions the situations such that each unique colour signifies that the situations with that colour have the same conditional transition distribution Collazo et al. [2018] for more details and discussion. Here each distinct partition will give rise to a different model $M_k \in \mathcal{S}$ our model space $k = 1, \ldots, K$, where $K$ is a large number based of the product of Bell numbers. Each CEG is then simply the bijective transformation of the staged tree as a coloured rooted graph [Shenvi and Smith, 2020]

2.2 Conjugate learning

In Collazo et al. [2018] it has been shown that for each $M_k \in \mathcal{S}$ we can set up priors consistently over $\mathcal{S}$ through the use of a product Dirichlet-Multinomial distribution. We are also able to perform a conjugate prior to posterior analysis on any complete random data set (no missing data) on $T$ which enables rapid computation of any candidate model.

For simplicity, the priors for our Dirichlet distributions are calculated by choosing an effective sample size, $\hat{\alpha}$, which assumes \textit{a priori} that all florets in the tree are uniformly distributed over all the florets and

\(^1\)If each variable has its own set within the hyperstage.
their corresponding edges.

2.3 Hyper-stage setting

In practice, we often find that many of the partitions of florets would not make sense. For example, obviously two situations with different numbers of emanating edges cannot be in the same stage. Less obviously, in any given context, for two edge probabilities to be assumed equal, we must be able to associate the meaning of these edges in some way. We note, for example, in all context-specific BNs, we implicitly assume that conditional probabilities can only be identical when the situations defined by their parents involve the same variables [Collazo et al., 2018].

When performing model search over CEGs, it is important, both from a modelling and a computational point of view, to restrict the search space so that only models that make sense within a given context are traversed and scored. Clearly, the choice of this restricted space can depend strongly on the domain.

To ensure all evaluated models are interpretable, we must use the concept of a hyperstage [Collazo, 2017]. A hyperstage, $H$, is a collection of sets containing the situations of an event tree $T$ such that any two situations $s$ and $s'$ can be in the same stage only if there is a set $H_i \in H$ such that $s, s' \in H_i$. We will be making the simplification that the hyperstage is a partition of the set of situations. This simplifies model selection as the staging of each set in the hyperstage is independent. Therefore, we can model fit to each separately.

2.4 Model selection

The HAC algorithm is a greedy search algorithm that begins with each situation as a separate stage then merges stages that provides the largest improvement in the model likelihood. This is done using one-nested CEGs which are CEGs in which one could be obtained from the other if two stages merged within it. The log Bayes factor (BF) of one-nested CEGs can be calculated by only considering situations in which their stagings are different [Freeman and Smith, 2011].

3 CEG Bayesian Model averaging

3.1 Bayesian Model Averaging

This section begins by providing a brief review of model averaging, as in Madigan and Raftery [1994]. When the focus of our inference is on $\Upsilon$ given data $y$ and models $M_k$, $k = 1, \ldots, K$,

$$p(\Upsilon | y) = \sum_{k=1}^{K} p(\Upsilon | M_k)p(M_k | y). \quad (1)$$

This shows that the prediction is the sum of the predictions of each of the $K$ models weighted by the probability of the models given the data.

For each model, $p(M_k | y)$ captures its posterior uncertainty.

3.1.1 Bayes factor

We can represent the posterior odds of two models as follows

$$\frac{p(M_k | y)}{p(M_l | y)} = \frac{p(y | M_k)p(M_k)}{p(y | M_l)p(M_l)}. \quad (3)$$

The BF is $BF_{k,l} = \frac{p(y | M_k)}{p(y | M_l)}$. Therefore we can represent Equation 2 as follows,

$$p(M_k | y) = \frac{BF_{k,1}p(M_k)}{\sum_{i=1}^{K} BF_{i,1}p(M_i)}. \quad (4)$$

As we set a uniform prior $p(M_i) = p(M_j)$ for all $i, j \in \{1, \ldots, K\}$, therefore

$$p(M_k | y) = \frac{BF_{k,1}}{\sum_{i=1}^{K} BF_{i,1}}. \quad (5)$$

This means that we are able to work out the model weighting based off all of the BFs against a first model.
3.2 Occam’s Window

Performing model averaging over all models is often an intractable problem due to the number of potential models. Therefore, when performing model averaging, it is useful to reduce the number of models considered; Occam’s window provides a way to do this. This is based on two steps: first, we remove any of our choice models that are \( \beta \) times less likely than the best performing model \( 2 \). We will refer to the remaining models as well-performing.

\[
S' = \left\{ M_k : M_k \in S \land \frac{\max_{M_l \in S} p(M_l | y)}{p(M_k | y)} < \beta \right\} \quad (6)
\]

Secondly, we discard any models that are nested in simpler, more likely models, as with Occam’s razor.

\[
R = \left\{ M_k : \exists M_l \in S', M_l \subset M_k, \frac{p(M_k | y)}{p(M_l | y)} < 1 \right\} \quad (7)
\]

\[
\hat{S} = S' \setminus R \quad (8)
\]

In Equation 7 we denote \( M_l \subset M_k \) if \( M_l \) is a nested model of \( M_k \).

3.3 Model averaging CEGs

We note that, when setting a uniform prior over a set of models, it is important that no models are represented twice. This is the case for the set of possible staged trees for a given event tree and hyperstage.

When dealing with interpretable models, Occam’s window is not just an approximation. It also effectively enables us to focus on good explanatory models and discard the rest. This is vital when there might be many poorly fitting models in the space \textit{a priori}; although none of these explains the process well, the residual probability on these remains large after sampling, which blurs the posterior image until we are able to gather enormous amounts of data. This will be the case when, for example, we do not have the time or expertise to forensically set priors on models that \textit{a priori} should be assigned a small probability.

4 Methodology

As the number of possible staged trees grows super-exponentially, performing model selection on the whole space is an intractable problem. In this paper, we propose the following approach to address this issue.

The basis of this idea is to first, run an algorithm many times to sample the space of models and return a set of well-performing models that perform close to the MAP. We then perform Bayesian model averaging on that set.

Our approach is to obtain a set of models that become a good approximation of Occam’s window. This provides a good narrative, across a few alternatives, that, under certain conditions, can be shown to provide a good approximation to the true set of models with highest associated posterior probabilities.

In this paper, we content ourselves with studying the performance of one of the simplest such search algorithms. We show that, even with this naive method, our search performs surprisingly well for the purposes of model averaging.

4.1 Weighted HAC

In this paper, we will be using a novel weighted version of the HAC algorithm, weighted hierarchical agglomerative clustering (w-HAC). However, instead of being a greedy search algorithm, it chooses the merging of situations stochastically, weighted by the BF of each choice based on Equation 9. This algorithm stops when there is no potential merging that increases the BF.

The probability of any two stages \( i \) and \( j \) merging, \( p(u_i, u_j) \), is given in Equation 9. Here, \( BF_{i \oplus j, 1} \) is the BF comparing when stages \( i \) and \( j \) are merged to when they are not. The calculation behind this is detailed in Equation 18. Pseudo-code for this algorithm can be seen Algorithm 1.

\[
p(u_i, u_j) = \frac{BF_{i \oplus j, 1}}{\sum_{k,l \in H} BF_{k \oplus l, 1}} \quad (9)
\]

This is a heuristic algorithm based around a simple modification to existing methods. This approach is
more efficient to implement than a method that requires exploring all possible stagings while exploring the space in a way that is likely to give high scoring models. It can be shown that, if w-HAC is run for long enough, then it will find the MAP estimate obtained from HAC, as w-HAC is the same as HAC if for every choice of merging the most probable merging is chosen i.e the one that increases the BF the most.

Due to the stopping criteria in the algorithm – either stopping if there are no possible situations left to be merged or if none of the potential mergers would increase the BF – we know that our set of solutions will satisfy a weaker version of Occam’s razor: it will not include a less probable model that is more complicated than a one-nested simpler model. This is because, due to the latter condition, if a simpler nested model existed, there would be a merged model with a positive BF. Therefore, a merging would occur.

The limitations of this algorithm and other even more robust hybrid search algorithms within this class of potential model selection algorithms are discussed in Section 6.

As with Occam’s window, we will remove all models that fall below a threshold \( \beta \) of the maximum likelihood achieved.

4.2 Independent hyperstage set staging

We have chosen to run w-HAC over the different sets within the hyperstage independently. This has two main benefits:

- We can explore the independence statements by observing the specific staging of that hyperstage.
- It allows us to focus our computational resources, exploring the sets in the hyperstage with many more elements and therefore many more possibilities of staging.

The set of CEGs that we are model averaging over is then given by all the permutations of the well-performing stagings of each set in the hyperstage.

These experiments were designed using modifications of a newly developed package used to model CEGs \(^3\). In order to run w-HAC over each set \( H_i \) in the hyperstage independently, we can modify the inputted hyperstage to one consisting of the set \( H_i \) with every other situation in its own set. This will affect the likelihood of the obtained CEG but, as the likelihood of each situation not in \( H_i \) will be the same for all models, when calculating the BF, the likelihood of the staging not within \( H_i \) will cancel out. As the BF is what determines the mergings that occur in w-HAC and the model weightings, this makes no difference to our output.

For set \( H_i \in H \), we have chosen to run w-HAC \( K \times \#(H_i) \) times. Here \( \#H_i \) is the number of elements in set \( H_i \) and \( K \) an arbitrary choice based upon computational resources. Therefore, the number of runs is proportional to the number of elements. We have chosen this approach, despite the fact that the number of possible stagings, and therefore the search space, rises much faster than the number of situations, because if we chose the number of runs as proportional to the number of stagings, all runs would be focused on the later stages due to the super-exponential growth of the Bell numbers.

4.3 Measure of separation

In order to quantify the separation between two models in our class, we define a measure of separation based on the partition of sets within our hyperstage. We define the partition, \( C_i \), of set \( H_i \in H \), in the following way,

\[
C_i = \{c_{1,1}, c_{1,2}, \ldots, c_{1,m}\}.
\]  

Here, each stage \( c_{i,j} \) contains the set of situations contained in the \( j \)th partition of set \( H_i \).

We define \( C_1 \preceq C_2 \) if all clusters in \( C_1 \) are subsets of clusters in \( C_2 \). Therefore \( C_1 \) is a refinement of \( C_2 \) and \( C_2 \) is a coarsening of \( C_1 \).

We can further define \( C_1 \land C_2 \) to be the partition that satisfies:

- All clusters in \( C_1 \land C_2 \) are contained in one cluster in \( C_1 \) and one cluster in \( C_2 \).

\(^3\)https://github.com/g-valley/cegpy
• It is the coarsest cluster that satisfies the first condition.

We can now define the following separation measure between two partitions $C_1$ and $C_2$:

$$s(C_1, C_2) = [\#(C_1 \land C_2) - \#(C_1)] + [\#(C_1 \land C_2) - \#(C_2)]$$  \hspace{1cm} (11)

It is critical to note that, as CEGs are an interpretable class of models, the hyperstage means that we only consider certain partitions of the situations into stages. As each partition corresponds to asserting probability distributions on corresponding florets, the same CEGs with close partitions will have similar interpretations.

5 Results

5.1 Stratified Example: CHDS Study

5.1.1 The Dataset

This example uses a dataset from the Christchurch Health and Development Study (CHDS), as detailed in Barclay et al. [2013]. This is a longitudinal cohort study, taking place over 30 years, of 1265 children born in mid-1977 in Christchurch, New Zealand. As in Barclay et al. [2013] and Cowell and Smith [2014], we are interested in the following 4 discrete variables for 890 children for which complete data was available:

• $X_S$ = family social background (High, Low), to henceforth be known as "social background"

• $X_E$ = family economic situation (High, Low), to henceforth be known as "economic situation"

• $X_H$ = child hospital admission, (Yes, No)

• $X_L$ = number of family life events, such as death of close relatives or divorce (Low, Average, High)

This dataset was chosen because an exhaustive search over all possible variable orderings has been performed in Cowell and Smith [2014] and therefore the MAP CEG is known.

5.1.2 The Input

In this paper, we will look at the fixed ordering $(X_S, X_E, X_H, X_L)$, which gave the best-performing CEG. The event tree used can be seen in Figure 7. As this is a stratified tree, we will be considering the trivial hyperstage, with each set containing the outcomes associated with each variable, as shown in Equation 12. To be consistent with Barclay et al. [2013] and Cowell and Smith [2014], we will be using $\alpha = 3$.

We will be running w-HAC over each hyperstage with $K$, the multiplier applied to the number of paths, as 1000. We chose a value of 20 for $\beta$, the cut off parameter for Occam’s window.

$$H = \{\{s_0\}, \{s_1, s_2\}, \{s_3, s_4, s_5, s_6\}, \{s_7, s_8, s_9, s_{10}, s_{11}, s_{12}, s_{13}, s_{14}\}\}$$  \hspace{1cm} (12)

5.1.3 Possible Stagings

The output of w-HAC on each set in the hyperstage gives only one staging relating to $X_E$ for $\{s_1, s_2\}$ as apart. For $\{s_3, s_4, s_5, s_6\}$, the staging associated with $X_H$, there were 3 potential stagings outputting by w-HAC; 2 are well-performing. For $\{s_7, s_8, s_9, s_{10}, s_{11}, s_{12}, s_{13}, s_{14}\}$, the staging associated with $X_L$, w-HAC outputted 14 potential stagings; 4 are well-performing.

For the sets in the hyperstage that had multiple well-performing stagings, their normalised BF can be seen in Figure 1 and Figure 2.

5.1.4 Model Averaging Weights

As for each set in the hyperstage, there are: 1, 1, 2 and 4 well-performing stagings respectively. Our model average is over the 8 possible combinations of those stagings. The weights for the 8 possible model averaged CEGs can be seen in Figure 3 (M1-8).

The MAP CEG can then simply be obtained by selecting the model with the highest weight. The MAP CEG can be seen in Figure 4.

{$s7$, $s8$, $s9$, $s10$, $s11$, $s12$, $s13$, $s14$}

Figure 2: Normalised BF ratios of the unique stagings of w-HAC algorithm for the hyperstage containing 
{$s7, s8, s9, s10, s11, s12, s13, s14$}.

5.1.5 Explanation of Results

As the output of the w-HAC algorithm only returned one staging on 
{$s1, s2$}, the staging relating to $X_E$, with the situations not merged. We can therefore conclude with some confidence that a family’s economic situation is not independent of their social background.

The two well-performing stagings shown in Figure 1 represent different independence statements about $X_H$ given by Equations 13 and 14. The first states that the frequency of hospital admissions is independent of social background and economic situation, as long as neither were low.

$$X_H \perp X_E, X_S | X_E \neq \text{low} \land X_S \neq \text{low} \quad (13)$$

The second independence statement, which was 1.4 times less probable, states that the frequency of hospital admissions is independent of economic situation.

$$X_H \perp X_E \quad (14)$$

We also note that, in all of the well-performing stagings, $s3$ and $s4$ are together. We are safe to assume that there can be little dependence between the arguments in Equation 15: given social background is low, the frequency of child hospital admissions is
independent of economic status.
\[ X_H \perp X_E | X_S \neq \text{high} \] (15)

These sorts of inferences can be generalised for any set of well-performing models by looking at their coarsest intersection. For example, for the potential stagings of \( X_L \) shown in Figure 2, the coarsest intersection is \{s10, s13, s14\}, \{s9, s7, s11\}, \{s12\}, \{s8\}.

Therefore, we can conclude with some confidence the following inferences:

- If social and economic background are low, the frequency of life events is not significantly dependent on a child going to hospital. This distribution of the life events appears very similar if a family has high social background, low economic background and the family has a child in hospital.

- If a child has not been to hospital, the frequency of life events is does not seem to depend significantly on social background and economic background, provided they are not both "low".

We can also quantify how separate these explanations are by saying they are all within a neighbourhood of distance 1, using the measure of separation defined in Equation 11 of their coarsest intersection.

We note that, through using model averaging, we have been able to identify those inferences from this data set which are most robust and appreciate how others appearing within the MAP model are less secure.

5.2 Non-Stratified Example: Falls

5.2.1 The Dataset

Here, we have a non-stratified CEG example based on simulated falls data for 1000 individuals aged over 65. Although simulated, this data was carefully constructed to be calibrated to the various studies of falls in the elderly [Shenvi et al., 2018].

The tree, which can be seen in Figure 8, is constructed from the following variables:

1. \( X_A \): Individual living situation and whether they have been assessed (Communal Assessed, Communal Not Assessed, Community Assessed, Community Not Assessed)
2. \( X_R \): Level of risk from a fall (High Risk, Low Risk)
3. \( X_{T1} \): If an individual has been refereed and treated (Not Referred & Not Treated, Not Referred & Treated, Referred & Treated)
4. \( X_{T2} \): If an individual has been treated (Not Referred & Not Treated, Not Referred & Treated)
5. \( X_F \): If a fall happened or not (Fall, Don’t Fall)

This is a non-stratified example because the process can unfold in a variety of ways. For example, for individuals that are not assessed for their risk of falls, it does not make sense to consider the outcome of their assessment. These stagings are all within a 2-neighbourhood of their coarsest intersection.

This dataset was chosen as it is simulated data in which the data-generating CEG is known.

5.2.2 The Input

Here, we will be running w-HAC over each hyperstage as shown in Equation 16. The 5 sets in the hyperstage correspond to the stagings associated with the variables. We chose \( K \) as 100 and a value of 20 for \( \beta \).

\[ H = \{\{s0\}, \{s1, s2, s3, s4\}, \{s5, s9\}, \{s6, s10\}, \{s7, s8, s11, s12, s13, s14, s15, s16, s17, s22, s23, s24, s25, s26\}\} \] (16)

We will again be using \( \alpha = 20 \), in line with the largest value tested in Shenvi and Smith [2019].

5.2.3 Possible Stagings

All sets bar one within the hyperstage gave a single model. They gave the following staging:
\{s0\}, \{s1\}, \{s2\}, \{s3\}, \{s4\}, \{s5, s9\}, \{s6, s10\}, \{s7, s8, s11, s12, s13, s14, s15, s16, s17, s22, s23, s24, s25, s26\}.
The set: 
\{s7, s8, s11, s12, s13, s14, s15, s16, s17, s22, s23, s24, s25, s26\} had 11 unique outputs of w-HAC; 3 were well-performing. The staging their normalised BF for this set can be seen in Figure 5.

### 5.2.4 Model Averaging Weights

As for only one set in the hyperstage there is more than one well-performing staging of the model, the model average is over three CEGs which only differ in that one set in the hyperstage. Therefore, the model average weights over the set of models is simply those of the weights of the staging shown in Figure 5.

Again, the MAP CEG can be obtained by selecting the best performing stagings of each hyperstage and can be seen in Figure 6.

```

Figure 6: The MAP CEG for the falls example.

#### 5.2.5 Explanation of Results

In the falls example, 4 of the 5 sets within the hyperstage the w-HAC algorithm outputted a single staging. For the 3 of 4 stagings which have non trivial stagings, we can conclude with some confidence the following inferences:

- The level of risk from a fall is likely to be different for individuals with either different living situations and assessment status.
- The outcome of the assessment for high risk individuals that were assessed does not significantly depend on living situation.
- The outcome of the assessment for low risk individuals that were assessed does not significantly depend on living situation.

The three well-performing stagings shown in Figure 3 represent different independence statements about the distribution of a fall happening, \(X_F\). The coarsest intersection of all of the stagings is given by 
\{\{s11, s13, s22, s7\}, \{s12, s16, s25, s8\}, \{s14, s15, s23, s24\}, \{s17, s26\}\}.

Therefore, we can be conclude with some confidence the following 3 independence statements:

- If an individual is high risk and not treated, the probability of falls appears not to depend significantly on their living situation.
- If an individual is low risk and not treated, the probability of falls does not appear to depend significantly on their living situation.
- If an individual is high risk and treated, the probability they fall does not depend significantly on either their living situation or whether or not they were referred.

These stagings are all within a 2-neighbourhood of their coarsest intersection.

### 6 Discussion

Firstly, because new software encoding CEGs has now become available, it is possible to quickly test
out new search algorithms, compare their efficacy and imagine new ones bespoke to the CEG class. Here we were able to demonstrate the efficacy of a particularly simple stochastic search algorithm that can be used instead of more standard greedy search algorithms to explore not only for the highest scoring models but their neighbourhoods so that we could better understand both model uncertainty and the robustness of inferences associated with a given selection.

It is of note that, despite the simplicity of the w-HAC algorithm, running it with the same prior and data as in previous studies enabled us to obtain the true MAP CEG, something that was not achieved by the HAC algorithm in Cowell and Smith [2014]. In the non-stratified example, the MAP CEG identified by the w-HAC algorithm was the CEG of the data generating process, as was the case for HAC.

As seen in the examples above, through exploring multiple well-performing models, we were able to explore the robustness of complex independence statements by comparing them to similarly performing models and extracting the explanations that are shared by them.

In the falls example, we demonstrate that the use of Bayesian model averaging techniques for CEGs is also applicable to the wider class of non-stratified CEGs. This enables our approach to be applied to a much wider set of possible domains in which models like BNs are wholly unsuitable.

We believe that, as all of our well-performing models are within small neighbourhoods of their coarsest intersection, we can extract most of the data generating process (except for those situations where the numbers passing through are small, or different florets have associated close probability distributions).

We also note that in our examples, the number of potential stages we obtained for each hyperstage was small, making analysis simple. For examples with a larger set of well-performing models, clusterings based on multidimensional scaling could be used to check for the existence of different explanations for the data.

There are, of course, many alternatives to the w-HAC algorithm to explore, many of which are likely to perform even better. Newly developed methods should satisfy various attractive consistency properties such as being able to search the space for highly separated models – and so very different possible high scoring explanations of how the data is generated, both in theory and practice. Potential further developments of w-HAC that satisfy this include: adding in a probability of merging, even if it will definitely lead to a decrease of the BF; or having a different starting point, on a random staging, instead of at the fully separated model.

The methods used in this paper are not specific to our choice of algorithm and are more broadly applicable to any model selection algorithm that searches the model space to obtain well-performing models.

The problem of efficient model selection for CEGs is an open one with further research needed. We hope that we have further motivated the need for such algorithms and note that the practical efficacy of these can be easily explored using newly available code.

In summary, we have shown that, even with a naive approach to exploring the model space, we can use Bayesian model averaging techniques on CEGs to provide a set of interpretable, well-performing models with which we can explore the robustness of their explanations.

Acknowledgements

The authors would like to thank John Horwood and the CHDS research group for providing the data set. Peter Strong was supported by the Engineering and Physical Sciences Research Council and the Medical Research Council grant EP/L015374/1. Jim Q. Smith was funded by the EPSRC [grant number EP/K03 9628/1]. We would like to thank Aditi Shenvi for her valuable comments.

References

A Model selection

In order to perform model selection using HAC and w-HAC, there are two equations used in the algorithm. Here, we provide a brief explanation of these for completeness; for the full detail, see Collazo et al. [2018]. The first is given in Equation 17 and gives the log marginal likelihood score $Q(C)$ for a CEG $C$:

$$Q(C) = \sum_{i=1}^{k} \left\{ \log g(\bar{a}_i) - \log (\bar{a}_i^*) + \sum_{j=1}^{k_i} (g(a_{ij}^*) - g(a_{ij})) \right\}$$

(17)

Here, $g(.) = \log \Gamma(.)$. $K$ is the number of stages. $\bar{a}_i$ is the sum of the parameter vector of the Dirichlet prior distribution for stage $i$. $\bar{a}_i^*$ is the sum of the parameter vector of the Dirichlet posterior distribution for stage $i$. $\alpha_{ij}$ is the $j$th element of the parameter vector of the Dirichlet prior distribution for stage $i$. $\alpha_{ij}^*$ is the $j$th element of the parameter vector of the Dirichlet posterior distribution for stage $i$.

The second equation, Equation 18, is related to calculating the Bayes factor of one-nested CEGs.

$$\log BF(C', C) =$$

$$g(\bar{a}_{i\oplus j}) - g(\bar{a}_i) - g(\bar{a}_j)$$

$$- g(\bar{a}_{i\oplus j}^*) + g(\bar{a}_i^*) + g(\bar{a}_j^*)$$

$$+ \sum_{l=1}^{k} \left\{ g(\alpha_{i\oplus j, l}^*) - g(\alpha_{il}^*) - g(\alpha_{jl}) - g(\alpha_{il}^*) + g(\alpha_{il}) + g(\alpha_{jl}) \right\}$$

(18)

Here, the $\alpha$ values have the same meaning as before, with $i \oplus j$ referring to the stage of the combined $i$ and $j$.

B w-HAC Algorithm

Input: Event tree $T$ its associated hyperstage $H$, data $y$ and root equivalent sample size $\bar{a}_0$.

Output: A CEG and its associated staging and log marginal likelihood score

Initialise $data$, $y_i$ for each situation $s_i$ in $T$ from $y$.

Initialise $priors$, $\alpha_i$ for each situation $s_i$ in $T$ from $\bar{a}_0$ through mass conservation.

Initialise a $stage$ for each situation $s_i$ in $T$

Set $score$ as the log marginal likelihood score given in Equation 17.

Set indicator $\leftarrow 1$.

while $indicator \neq 0$ do

for every pair of stages in stages in the same hyperstage do

Calculate the $logBF$ as given in Equation 18 comparing the structures of merging the pair compared to keeping them apart, all other stages being equal.

if no such pair exists then

1. indicator $\leftarrow 0$

end

end

if There exists a calculated $logBF > 0$ then

choose a pair $u_i$ and $u_j$ weighted by their $BF$ as in Equation 9

for pair $u_i$ and $u_j$ do

score $\leftarrow$ score $+$ log $BF(u_i, u_j)$

Update stages to add stage $u_{i\oplus j}$ and remove stages $u_i$ and $u_j$.

Update data to add $y_{i\oplus j} = y_i + y_j$ and remove $y_i$ and $y_j$.

Update priors to add $\alpha_{i\oplus j} = \alpha_i + \alpha_j$ and remove $\alpha_i$ and $\alpha_j$. end

end

else

1. indicator $\leftarrow 0$

end

end

return stage, score
