(Dated: March 15, 2022)

This article offers a detailed analysis of pseudo-phase transitions of Ising and Baxter-Wu model in the two-dimensional finite size lattices. We carry out Wang-Landau sampling to obtain the density of states. Using microcanonical inflection-point analysis with the microcanonical entropy, we obtain the order of the pseudo-phase transitions in the models. The microcanonical analyzing results of second order transition for Ising model and the first order transition for Baxter-Wu model are well consistent with the traditional canonical results. In addition, the third-order transitions are found in both models implying the universality of higher order phase transitions.

I. INTRODUCTION

Traditionally, phase transitions refer to analytic discontinuities or singularities in the thermodynamic functions of systems which satisfy the thermodynamic limit[1]. Landau’s phenomenological theory successfully describes all second-order phase transitions in mean-field sense. In 1971, Wilson introduced the concept of a renormalization group into the theory and interpret the scaling laws and the universality class[2]. In the construction of the theory, Ising model, which could be solved exactly, played a crucial role[3]. This model provide the criterion to judge the precise of theories for phase transitions. Generally, models which are more complicated than Ising model could not be solved exactly. Monte Carlo simulations as powerful tools offer numerical methods for calculating the thermodynamic functions[4]. Though computer simulations could not be done on infinite system, one can obtain the precise critical behaviors and transition temperatures via finite size analyze. By changing the size of the system, one can get the scaling behavior of the singular part of the free energy and the thermodynamic properties. The most existing simulation studies have revealed the behaviors under the thermodynamic limit. However, with the development of the nanoscience, biophysics and network science, many small systems draw tremendous attentions. In the BW model display the discontinuities due to the low frequency large energy fluctuations[16, 17]. In addition to being applied to the fields of magnetism and surface adsorption, the BW model was used to study the dynamics of social balance[18] and the satisfiability problem of computer science[19] in the field of complex networks. The canonical methods[16] pointed out that the internal energy histograms of the single layer 2D spin-1/2 BW model have double peaks, which suggest the pseudo-first-order phase transitions at the finite size systems. The reason for the phenomenon is the system is in a metastable states of coexistence of ferro- and ferrimagnetic order. Moreover, Jorge et. al investigated the spin-1 the phase transition of Baxter-Wu and found more complicated behaviors[20].

It should be necessary to study the finite BW model with the perspective of microcanonical inflection-point analysis. In this article, we use Wang-Landau method to obtain the DOSs of Ising model and Baxter-Wu model. Ising model is used to certify the correctness of the DOS obtained via Wang-Landau sampling. In Sec 2, we briefly describe the models and the methods. The results are shown in Sec. 3, with some discussion. Sec. 4 gives the conclusions of our work.
where, the spin variables are located at the vertices of the angular lattices is

\[ E = -J \sum_{<ij>} s_i s_j \] (1)

where \( s_i = \pm 1 \) stands for the spin located in the lattices, and \( <ij> \) denotes the summations over the nearest neighbor sites. We only investigate the ferromagnetic model, so \( J > 0 \). If one spin of the lattice flips, it leads to the 4\( J \) energy difference in most cases. There are two exceptions that the differences between the ground state and the first excited state, and highest energy level and second-to-last energy level are 8\( J \). As a result, there are \( N^2 - 1 \) energy levels in this model.

The Hamiltonian of the BW model in the \( N \times N \) triangular lattices is

\[ E = -J \sum_{<ijk>} s_i s_j s_k \] (2)

where, the spin variables are located at the vertices of the lattice. \( <ijk> \) denotes the product of the three spins on the elementary triangle, and the sum is over all triads \( <ijk> \). We also study the case of \( J > 0 \). For spin-\( \frac{1}{2} \) one spin flipping leads to 4\( J \) energy difference in most cases as well. However, the differences between the ground state and the first excited state, and highest energy level and second-to-last energy level are 12\( J \). Therefore, the spin-\( \frac{1}{2} \) model has \( N^2 - 3 \) energy levels. If we consider the spin-1 BW model, which the spin can take \(-1, 0, 1\), the energy levels are more complicated, there are 4\( N^2 - 10 \) levels. The reason for this behavior is that the energy differences of the first and the last seven levels are 6\( J \), 4\( J \) or 2\( J \), while the other differences are \( J \).

**B. Wang-Landau sampling**

We carry out Wang-Landau sampling\(^{[21]} \) to obtain the density of states \( g(E) \). The Wang-Landau sampling is a powerful algorithm to estimate \( g(E) \) directly by random walking in the energy space with a flat histogram. we start with \( g(E) = 1 \), and improve it in the following way. The random walk is then performed according to the probability

\[ p\left(E_1 \rightarrow E_2\right) = \min\left\{ \frac{g(E_1)}{g(E_2)}, 1 \right\} \] (3)

where \( E_1 \) and \( E_2 \) is the energy level before flipping and that would result if the spin were flipped. The density of states is updated by

\[ g(E) \rightarrow g(E)f \] (4)

where \( E \) is the energy level of the accepted state, and \( f \) is a modification factor of which initial value is \( f = f_0 = e^{-2.71828} \). Meanwhile, the energy histogram \( H(E) \) plus 1. We proceed with the random walks until histogram of energies is "flat", which means that the histogram for all possible energies is not less than 80% of the average histogram in this paper. Then the modification factor is reduced, \( f_{i+1} = f_i^2 \), reset histogram to \( H(E) = 0 \) for all values of \( E \), and restart the random walks. The simulation is stopped when the modification factor is smaller than \( f_{\text{final}} = 1 + 10^{-8} \).

The advantage of the method is avoiding the critical slow down. However, sampling the full range of energies of a large system with complex energy landscape is quite difficulty using a single walk\(^{[22]} \) because get "flat" histogram of the energies need very long time simulations. Vogel et al suggest the replica exchange Wang–Landau\(^{[23–26]} \), which is suitable to study the large system with long energy range and complex landscape. This algorithm split the energy range into many smaller sub-windows with large overlap between adjacent windows. We carry out WL sampling in each energy sub-window with multiple independent walkers. 75% overlap is chosen in this work. After a certain number of Monte Carlo steps, a replica exchange is proposed between two random walkers. Suppose \( i \) and \( j \) are random walkers of two adjacent energy window, and \( \{s_i\} \) and \( \{s_j\} \) are the configurations that the walkers \( i \) and \( j \) are carrying before the exchange. The acceptance probability \( P_{\text{acc}} \) for the exchange of configurations \( \{s_i\} \) and \( \{s_j\} \) between walkers \( i \) and \( j \) is

\[ P_{\text{acc}} = \min\left\{ 1, \frac{g_i(E(\{s_i\}))g_j(E(\{s_j\}))}{g_i(E(\{s_j\}))g_j(E(\{s_i\}))} \right\} \] (5)

In order to calculate a single \( g(E) \) over the entire energy range we chose the joining point for any two overlapping density of states pieces where the inverse microcanonical temperatures \( \beta = d\log[g(E)]/dE \) best coincide. The convergence of \( g(E) \) is speeded up for the smaller energy range of the sub-window.

**C. Microcanonical infection-point analysis method**

Qi and Bachmann combined the microcanonical infection-point analysis and the principle of minimal sensitivity to identify and classify first- and higher-order transitions in complex systems of any size\(^{[9]} \). Using this analysis, they found that the two-dimensional ferromagnetic Ising model exhibits signals of transitions other than the single second-order phase transition. 3rd-order independent and dependent transition were observed in the systems. They also obtained the phase diagram for a grafted lattice polymer interacting with an adhesive surface.

The basic idea is that the macroscopic behaviors of a physical system are governed by the quantities entropy

and energy. The microcanonical entropy, which contains the complete information about the phase behavior of a system, can be defined as

$$S(E) = k_B \ln g(E)$$  \hspace{1cm} (6)

where $k_B$ is the Boltzmann constant. The entropy and its derivatives are monotonic functions within energy regions associated with a single phase. However, a phase transition would break the monotony, and is singled by an inflection point. According to the principle of minimal sensitivity, only least-sensitive inflection points have a physical meaning. For example, if $S(E)$ has a least-sensitive inflection point, its first derivation, $\beta(E) = T^{-1}(E) = \frac{dS(E)}{dE}$ which is the microcanonical inverse temperature, should contain a positive valued maximum slope. $\gamma(E) = \frac{d\beta(E)}{dE} = \frac{d^2S(E)}{dE^2}$ has a positive maximum, which gives a signal of the first order phase transitions. If $\beta(E)$ has a least-sensitive inflection point, its first derivation, $\gamma(E)$ should contain a negative maximum, which reveals a second-order phase transition. $\delta(E) = \frac{d\gamma(E)}{dE} = \frac{d^3S(E)}{dE^3}$ would give the information of a third-order phase transition.

In addition to the class of independent transitions, there is another category, dependent transitions which can be identified by this method as well. We summary the method in Table II.

III. RESULTS

The purpose of this work is to identify the order of the phase transitions for the finite Ising and BW systems. To certify the correctness of our work we calculate the value of specific heat and compare it with the $\gamma(E)$. Then the curves of $\delta(E)$ are used to locate the third order transitions for the models studied in our work.

A. Ising model

The lattice sizes we simulate are from $N = 32$ to $N = 96$. The microcanonical entropies and their derivations are shown in Fig. II. There exist negative maximums of the curves of $\gamma(E)$, which suggest the second phase transitions. We also locate the transition points using canonical method. With the DOS in hand, we can calculate the specific heat via $c_V = \frac{<E^2>-<E>^2}{Nk_BT^2}$, where $<E> = \sum_E g(E) \exp(-E/k_BT)$. The transition points are located with the maximums of the specific heat. The results are displayed in the following Table II. The second row gives the points obtained by microcanonical analysis and the third row gives the results obtained by specific heat. The results are well agreement with each other $\delta(E)$ show the positive minimum in Fig. II when $N = 96$, which suggest the independent third-order transitions. The location is $e = -1.469$. Moreover, when the size is small, there exit inflection-points suggesting the fourth-order transitions. However, we could not locate the points precisely because the higher order derivatives amplify the noise of the simulation.

The 3rd dependent transition signals are detected as well. The curves for $\delta(E)$ have the negative maximums which can determine the third transition points. The points are shown in the Table III.

The transition points obtained with microcanonical and canonical methods coincide well and are agreement with the results of Qi et. al.’s work [9] showing that it is reliable to perform microcanonical infection-point analysis up to third order transition using the DOS obtained by Wang-Landau sampling.
B. Baxter-Wu model

The BW model in triangular lattice has four degenerate ground states, and has longer energy range for spin-1/2 model. Hence, the simulating lattice sizes are from \( N = 30 \) to \( N = 90 \) for the spin-1/2 model and from \( N = 18 \) to \( N = 60 \) for the spin-1 model.

Using our obtained data of the DOS, we calculate the specific heat and analyze the finite size effect. We get the critical exponent \( \alpha/\nu \) equals to 1.022 ± 0.005 for spin-1/2 model while to 1.120 ± 0.006 for spin-1 model. Spin-1/2 model belongs to the universality class of 4-state Potts of which the exponent nearly equals 1. However, the exponent for spin-1 model is larger than 1 which suggests that the behavior of thermodynamic limit of this model is nontrivial.

![Graphs showing the behavior of different quantities for BW model](image)

Fig. 1. a) The logarithm of the density of states, b) inverse temperature \( \beta(e) \), the first and the second derivations of inverse temperature c) \( \gamma(e) \) and d) \( \delta(e) \) for Ising model.

The microcanonical results for spin-1/2 and 1 BW models are displayed in fig. 3. The non-monotonic ”backbending” of inverse temperature \( \beta \), which is a typical signal of phase coexistence, is observed in both spin-1/2 and 1 model. The positive maximum values of \( \gamma \) reveal the first order phase transitions of which the positions locate the transition points. As the lattice size increases, the values of \( \gamma \) become smaller implying the decrease of the ”latent heat”. The result is consistent with the results of the canonical analysis showed in fig 2 a) and c).

Moreover, the signals of the third order phase transitions appear in the curves of fig 3 c) and f). Similar to the Ising model, both the independent and dependent transition are detected. The curves of \( \delta(E) \) have positive minimums and negative maximums. Table IV gives the locations of the third-order phase transitions. \( \beta a, b \) stands for the transition inverse temperature, where \( a \) denotes the spin 1/2 or 1 and \( b \) the type of the transitions. \( d \) is for dependent transition and \( in \) for independent transition.

Due to the existence of the latent heat of the pseudo first order transitions, the higher order phase transition show some difference from the system with the second order transition. The positions of the third order independent phase transitions is at the energy levels lower than the positions of the first order phase transition, while the positions of the dependent phase transitions is at higher energy levels. The inverse temperature \( \beta \) has non-monotonic ”backbending” phenomenon, and the locations of the third transitions are in the region of the backbending which leads to the close positions between the independent and dependent transitions. In addition,
the independent transitions refer to the transitions between the over heated states with higher order and the metastable states with the low order, while the dependent transitions refer to the transitions between supercooled lower order metastable states and the disorder states. The third order phase transitions occur in the region of the coexisting phase, hence, the positions of the independent and dependent transitions are very close.

IV. CONCLUSION

In summary, we use Wang-Landau sampling to obtain the DOS for Ising and BW model. Then, the order of the pseudo transitions for the finite size systems are analyzed via microcanonical inflection point method. We compare the microcanonical results with the canonical ones as well. The data for the Ising model reveal that the DOS obtained with Wang-Landau sampling can be used for analyze the order transitions up to third order, and the positions of the second and third order transitions are obtained precisely. Based on the reliability of the method, we study the spin-1/2 and 1 BW model. The data show that the finite size BW models have the first and third transition. The "latent heat" of the first order transitions decreases as the system sizes become larger. We conjecture that the "latent heat" disappear at the thermodynamic limit. In addition, there exist the third order phase transition in both Ising and BW model which imply the universality for the higher order transitions to some extent. It would be interesting to confirm the universality of the third order phase transition in different spin models and reveal the origin of the higher than second order transitions.
