(Dated: March 16, 2022)

We study analytically and numerically the self-organization of mixtures of run-and-tumble bacteria whose motilities are regulated by quorum-sensing interactions. We show the emergence of rich spatial structures, including static and dynamic patterns. We derive a microscopic condition for restoring action-reaction at the macroscopic scale, which endows the system with an effective free energy functional. The latter allows us to rationalize the static patterns observed in our simulations and to predict the corresponding phase diagram. In the presence of non-reciprocal interactions, we derive a sufficient condition to observe the emergence of travelling patterns.

The self-organization of motile entities is a problem of great importance in a large variety of topics, ranging from morphogenesis to the design of active materials, which has led to a recent upsurge of studies on the collective behaviors of mixtures of active particles [1–14]. For motile microorganisms, chemotaxis has been demonstrated as an important pathway towards pattern formation [15–17]. More recently, the regulation of bacterial motility by the local density of their peers has been suggested as an effective alternative towards spatial organization [18–20]. Such interactions, which we refer to as quorum sensing (QS) [21, 22], are generic in nature, where they are typically mediated by diffusing signalling molecules. Interestingly, QS can also be engineered in the lab, for instance using light-controlled self-propelled colloids [23, 24], paving the way towards engineering soft active materials.

However, since self-propelled particles are out of equilibrium, we lack a general theory to predict the collective properties emerging from QS interactions and existing results are scarce. For single-component systems, the slowdown of the particles as their density increases triggers a motility-induced phase separation (MIPS), leading to the coexistence between dilute, active regions and dense, arrested ones [20, 23, 25, 26]. For mixtures of two bacterial strains, richer forms of organizations have been reported recently, with demixing or colocalization between the strains depending on whether a mutual enhancement or inhibition of motility is at play [27]. Beyond this specific example, the range of possible patterns resulting from QS interactions remains poorly explored. In particular, while much recent work has explored non-reciprocal interactions in active matter [1, 7, 8, 12, 14, 28–31], their role in bacterial ecosystems has not been studied.

In this Letter, we study the self-organization of bacterial strains whose motilities are regulated by quorum-sensing interactions. Using microscopic simulations of run-and-tumble particles (RTPs), we show that a large range of collective behaviors can be observed, including both static and traveling patterns. To rationalize our results, we coarse-grain the microscopic dynamics into a fluctuating hydrodynamic theory that describes the spatiotemporal evolution of the ecosystem. We look for Lyapunov functionals—or effective free energies—and show that these exist for a certain type of reciprocal interactions. Our results thus show how the action/reaction principle can be generalized to a many-body, mediated interaction like QS. They also allow us to account for the static patterns observed in our numerics, relating the detail of the microscopic interactions to the self-organization of the ecosystem, and predict the corresponding phase diagram with a high level of accuracy. Finally, when the mapping to equilibrium breaks down, we show the emergence of a variety of travelling patterns, which include steady as well as chaotic band phases.

Self-organization of mixtures of RTPs interacting via quorum sensing. We consider $N$ species of RTPs and denote by $\rho_\mu(\mathbf{r})$ the density field of species $\mu$. Quorum-sensing interactions between the species lead to the following dynamics for particle $i$ of species $\mu$:

$$\dot{\mathbf{r}}_{i,\mu} = v_\mu(\mathbf{r}_{i,\mu}[\rho_\nu]) \mathbf{u}_{i,\mu},$$

where $\mathbf{u}_{i,\mu}$ is the orientation of the particle and the self-propulsion speed $v_\mu$ is generally both a function of $\mathbf{r}_i$ and a function of all density fields. In addition, $\mathbf{u}_{i,\mu}$ undergoes instantaneous tumbling events at rate $v_\mu^{-1}$, after which a new orientation is sampled uniformly. For sake of generality, we allow both for global interactions, where $v_\mu$ depends on the total density field of particles $\rho_{\text{tot}}(\mathbf{r}) = \sum_\mu \rho_\mu(\mathbf{r})$, and for specific ones, where $v_\mu$ depends specifically on one—or more—density field $\rho_\nu(\mathbf{r})$. In the latter case, we refer to self and cross interactions when $\mu = \nu$ and $\mu \neq \nu$, respectively. To explore the collective behaviours emerging from these interactions, we have carried out microscopic simulations of two interacting species of RTPs, denoted by $\alpha$ and $\beta$ below; the results are summarized in Fig. 1.

First, we consider self-inhibition of motility coupled to a global enhancement of motility through

$$v_\mu(\mathbf{r}) = v_\mu^0 \phi_\mu[\rho_\mu(\mathbf{r})] \phi_\nu[\rho_{\text{tot}}(\mathbf{r})],$$
interactions according to
\[ v_\mu(r) = v_\mu^0 \phi_\mu^s(\rho_\mu(r)) \phi_\mu^c(\rho_\nu(r)) , \]  
(3)
where \( \phi_\mu^s(\rho) = \exp[\kappa_\mu^s S_\mu^s(\rho)] \). We consider opposite interactions between the species: \( \kappa_\alpha^s < 0 \) makes \( \beta \) inhibit the motility of \( \alpha \) while \( \kappa_\beta^s > 0 \) causes \( \alpha \) to enhance the motility of \( \beta \). As shown in Fig. 1d and SM Movies 1–3, a rich variety of steady or chaotic dynamical patterns are then observed.

**Fluctuating hydrodynamics.** To account for the emerging phenomenology of our active mixtures, we coarse-grain their microscopic dynamics. The hydrodynamic fields are the fluctuating conserved density fields \( \rho_\mu(r) = \sum_j \delta(r - r_{j,\mu}) \), whose dynamics in \( d \) space dimensions can be obtained as Itô-Langevin equations \[ \partial_t \rho_\mu = -\nabla_r \cdot \left[ V_\mu \rho_\mu - D_\mu \nabla r \rho_\mu + \sqrt{2 D_\mu} \rho_\mu \Lambda_\mu \right] , \]  
(4)
where the \( \Lambda_\mu(r,t) \) are \( N \) independent centered Gaussian white noise fields of unit variance and independent components, and the collective diffusivities and drifts read
\[ D_\mu = v_\mu^2(\{\rho_\nu\}) d\tau^{-1} , \quad V_\mu = -v_\mu \nabla v_\mu(\{\rho_\nu\}) d\tau^{-1} . \]  
(5)

Inspection of Eq. (4) shows that it can be rewritten as
\[ \partial_t \rho_\mu = \nabla_r \cdot \left[ M_\mu \nabla u_\mu + \sqrt{2 M_\mu} \Lambda_\mu \right] , \]  
(6)
where \( M_\mu(r) = \rho_\mu(r) D_\mu(r,\{\rho_\nu\}) \) is a density-dependent collective mobility and \( u_\mu(r) = \log[\rho_\mu(r) v_\mu(\{\rho_\nu\})] \) is an effective chemical potential.

**Reciprocal interactions and effective equilibrium.** To gain insight into the fluctuating hydrodynamics (6), it is interesting to look for the existence of a Lyapunov functional \( F \). In particular, when \( u_\mu(r) = \frac{\delta F}{\delta \rho_\mu(r)} \) it is easy to see that \( \partial_t (F) = - \int dr \sum_\mu (M_\mu(\nabla \delta \rho_\mu))^2 < 0 \). The functional \( F(\rho_1, \ldots, \rho_N) \) is then mathematically equivalent to a free energy in equilibrium. To determine the conditions under which such an effective free energy exists, we need to extend the functional Schwartz theorem to the space in which the density fields \( \{\rho_\mu\} \) live \[ \text{[33, 34]} \]. This leads to the requirement that the distribution
\[ D_{\mu\nu}(r,r') = \frac{\delta u_\mu(r)}{\delta \rho_\nu(r')} \frac{\delta u_\nu(r')}{\delta \rho_\mu(r)} . \]  
(7)
must vanish for every pair \( (\mu,\nu) \).

When the self-propulsion speeds depend exclusively on the local densities, i.e. \( v_\mu(r) = v_\mu(\rho_1(r), \ldots, \rho_N(r)) \), the condition (7) leads to:
\[ \frac{\partial \log v_\mu}{\partial \rho_\nu} = \frac{\partial \log v_\nu}{\partial \rho_\mu} . \]  
(8)
The solutions of Eq. (8) are generated by all potentials \( U(\rho_1, \ldots, \rho_N) \) by setting \( \log v_1, \ldots, \log v_N \) = \( \nabla_\rho U \),
where $\nabla_p U|_\mu \equiv \frac{\partial U}{\partial \rho_\mu}$. The effective free energy is then given by
\begin{equation}
\mathcal{F}[\{\rho_\mu\}] = \int d\mathbf{r} f(\mathbf{r}) = U(\{\rho_\mu(\mathbf{r})\}) + \sum_\mu \rho_\mu(\mathbf{r}) \log \rho_\mu(\mathbf{r})
\end{equation}

All microscopic active dynamics defined by Eq. (1) such that Eq. (8) holds are thus equivalent, at the macroscopic scale and under the assumption of locality, to passive mixtures whose dynamics read
\begin{equation}
\dot{\mathbf{r}}_{i,\mu} = -\nabla_{\mathbf{r}_{i,\mu}} U(\{\rho_{j,\nu}\}) + \sqrt{2D_\mu} \eta_{i,\mu},
\end{equation}

where the total potential energy $U(\{\rho_{j,\nu}\}) \equiv \int d\mathbf{r} U(\{\rho_{\nu}(\mathbf{r})\})$ depends on the $\mathbf{r}_{j,\nu}$ through the fluctuating fields $\rho_{\nu}(\mathbf{r})$.

Let us now show how this mapping to equilibrium accounts for the phenomenology of our first example, illustrated in Figs 1a-c. Under a local approximation, $\tilde{\rho}_\mu(\mathbf{r}) \simeq \rho_\mu(\mathbf{r})$ and Eq. (2) becomes $\log v_\mu = \log g_\mu^{\varphi_{\alpha,\beta}}(\rho_{\alpha}) + \kappa^{\varphi_{\alpha,\beta}}(\rho_{\alpha,\beta}) \log \rho_{\alpha}(\mathbf{r})$. Direct inspection shows that Eq. (8) then amounts to $\kappa^{\varphi_{\alpha,\beta}} S^\varphi_{\alpha,\beta} = \kappa^{\varphi_{\alpha,\beta}} S^\varphi_{\alpha,\beta}$ for all $\mu, \nu$: the sole requirement for effective equilibrium is that the global interaction term $\phi^{\varphi_{\alpha,\beta}}$ be common to all species. This is the case for the system shown in Fig. 1a-c, which can thus be mapped onto an equilibrium problem. Our choice of sigmoidal function for $S^\varphi_{\alpha,\beta}$ then leads to a free energy given by Eq. (9)-(10) with
\begin{equation}
U(\rho_\alpha, \rho_\beta) = 2\kappa^{\varphi} \delta \rho_0 \log \left[ \frac{\cosh \left( \frac{\rho_{\alpha 0} - 2\bar{\rho}}{2\delta \rho} \right)}{\cosh \left( \frac{\rho_{\beta 0} - 2\bar{\rho}}{2\delta \rho} \right)} \right] + \sum_{\mu = \alpha, \beta} \kappa^{\varphi} \delta \rho_0 \log \left[ \frac{\cosh \left( \frac{\rho_{\mu 0} - 2\bar{\rho}}{2\delta \rho} \right)}{\cosh \left( \frac{\rho_{\mu 0} - \bar{\rho}}{\delta \rho} \right)} \right],
\end{equation}

where we have introduced $\kappa^\varphi \equiv \kappa^{\varphi_{\alpha,\beta}} = \kappa^{\varphi}_{\alpha,\beta}$ [35].

The self-organization of the two coexisting species can then be predicted from the analysis of the free energy (9). Departure from a homogeneous, well-mixed system is predicted whenever the free energy density (10) is not convex. Coexisting densities can then be predicted by constructing the tangent planes of $f(\rho_{\alpha}, \rho_{\beta})$. We use this to obtain the phase diagram in composition space $(\rho^0_{\alpha}, \rho^0_{\beta})$ corresponding to the parameters of Fig. 1a-c and compare to numerical measurements of coexisting densities (Fig. 2a). Despite the construction relying on a locality assumption and a mean-field approximation, the agreement is excellent. The triple coexistence regime reported in Fig. 1c emerges when the free energy surface admits a plane that is tangent in three points $(\rho^0_{\alpha}, \rho^0_{\beta})$ simultaneously, as illustrated in Fig. 2b. The corresponding compositions then delimit the coexistence region and determine the coexisting phases. As in an equilibrium system, the respective fraction of each phase is determined by a lever rule. Despite the underlying approximations, the equilibrium mapping thus accounts for the static phase-separation scenario reported in Fig. 1. A natural question—to which we now turn—is then how violation of condition (8) may lead to an emerging physics that explicitly breaks time-reversal symmetry.

Non-reciprocal interactions and dynamical patterns. Non-reciprocal interactions are characterized by the breakdown of Newton’s third law, which states that if particle $i$ exerts a pairwise force $f_{ij}$ onto particle $j$ then momentum conservation imposes that $f_{ji} = -f_{ij}$. Active systems exchange momentum with their environment and are thus free of this constraint. Non-reciprocal interactions between active particles have indeed been predicted theoretically and shown to lead to a rich variety of phenomena [1, 7, 8, 12, 14, 28–31].

For active particles, pairwise interactions are actually an idealized limit and most interactions like quorum-sensing or chemotaxis are complex, mediated interactions. Defining an action-reaction principle in this context is then non-trivial. Let us consider the condition (8) under which our microscopic dynamics maps onto a \textit{a bona fide} equilibrium problem. Even in this case, the contribution of particle $i_\mu$ to the velocity field $\mathbf{f}_{j,\nu}$ of particle $j_\nu$ is not equal and opposite to the contribution of particle $j_\nu$ to $\mathbf{f}_{i,\mu}$. Equation (8) can then be seen as a non-trivial \textit{microscopic constraint} on the QS interaction such that action-reaction is restored at the \textit{macroscopic scale} of the fluctuating hydrodynamics (6).

When Eq. (8) is violated, we may look for the possibility of dynamical patterns. To get some insight into the possible emergence of travelling solutions, we consider the fate of perturbations around homogeneous solutions of Eq. (6), $\rho_{\mu}(\mathbf{r}) = \rho^0_{\mu} + \delta \rho_{\mu}(\mathbf{r})$. In Fourier space, their linearized dy-
namic read \(\partial_t \delta \rho_{\mu}(\mathbf{q}) = -\mathbf{q}^2 \mathcal{M}_{\mu\nu}(\mathbf{q}) \delta \rho_{\nu},\) with
\[
\mathcal{M}_{\mu\nu}(\mathbf{q}) = D_\mu^0 \left[ \delta_{\mu\nu} + \rho_\mu^0 \frac{\partial}{\partial \rho_\nu} \log v_\mu \right].
\] (13)

For \(N = 2\) species, straightforward algebra shows that eigenvalues with non-vanishing imaginary parts require [36]
\[
\frac{\partial v_\beta}{\partial \rho_\alpha} \frac{\partial v_\alpha}{\partial \rho_\beta} < 0.
\] (14)

Linear stability analysis thus predicts an oscillatory behaviour when the two species interact in opposite ways, say when species \(\beta\) enhances the speed of \(\alpha\) while \(\alpha\) inhibits the motility of \(\beta\). Under this condition, which is a stronger requirement than simple non-reciprocity, homogeneous profiles are linearly unstable whenever
\[
\sum_{\mu = \alpha, \beta} D_\mu(1 + \rho_\mu^0 \frac{\partial}{\partial \rho_\mu} \log v_\mu) < 0.
\] (15)

This opens up the possibility of travelling patterns, which we now explore.

To do so, we consider the dynamics (3) in which both species self-inhibit their motilities and experience non-reciprocal cross interactions. We use self-inhibitions strong enough that in the absence of cross-interactions each species undergoes MIPS independently, hence enforcing Eq. (15). Figure 3 shows the phase diagram obtained by varying the cross-interactions via \(\kappa_\alpha^\beta\) and \(\kappa_\beta^\alpha\). In agreement with our prediction (14), travelling patterns are only observed when \(\kappa_\alpha^\beta \kappa_\beta^\alpha < 0\) (orange quadrants). An intuitive understanding of the observed phases can be achieved by noticing that each species tends to accumulate where it goes slower [25, 37–41]. Motility inhibition then acts as an effective attraction whereas motility enhancement leads to effective repulsion. When \(\kappa_\alpha^\beta \kappa_\beta^\alpha\) are both positive, the species effectively repel each other, leading to a triple coexistence regime with demixing between the dense phases (red quadrant). Negative \(\kappa_\alpha^\beta \kappa_\beta^\alpha\), on the other hand, lead to attractive interactions and colocalization of the liquid phases (blue quadrant). The frustrated case \(\kappa_\alpha^\beta \kappa_\beta^\alpha < 0\), finally, leads to a complex run-and-chase dynamics between the two species that results in steady (orange square, SM movie 2) or chaotic (orange star, SM movie 1) travelling bands when \(|\kappa_\alpha^\beta| \approx |\kappa_\beta^\alpha|\), as well as to a variety of more complex dynamical behaviors in less symmetric cases (orange cross, pentagon and hexagon as well as SI movie 3-5). Finally, while the presence of self inhibition allows one to rationalize the emergent behaviours reported in Figure 1d and 3, non-linear dynamical patterns can also arise outside the predictions of the linear stability analysis [32].

**Conclusion.** In this Letter we have shown how quorum-sensing interactions lead to a rich phenomenology in mixtures of run-and-tumble particles. Already at the level of binary mixtures, we have shown how such systems can self-organize into complex static and dynamical patterns. By coarse-graining the microscopic dynamics into a macroscopic field theory, we have been able to account for the emerging phases. In particular, we have derived a microscopic condition for the field theory to map onto an equilibrium problem, which generalizes the action/reaction principle to quorum-sensing interactions. Using a tangent plane construction on the corresponding effective free energy (9), we were able to accurately predict the phase diagram measured in microscopic simulations.

When the reciprocity condition (8) is violated at the microscopic level, one can show that the fluctuating hydrodynamics (6) is irreversible and leads to a positive entropy production rate (see section X of [32]). When the cross interactions between species are opposite to each other, a run-and-chase dynamics sets in at the macroscopic scale, leading to rich dynamical patterns. These patterns are reminiscent—though not identical—to those predicted recently using non-reciprocal Cahn-Hilliard equations [7, 8]. For instance, the periodic travelling waves reported in [7, 8] seem to be replaced by band chaos in our microscopic simulations. A full non-linear study of the macroscopic field theories describing active mixtures, whether at mean-field level or including fluctuations, thus remains an important open problem. Furthermore, characterizing the non-equilibrium probability currents outside the regime of dynamical patterns is an open challenge that could be tackled using recent extension of differential geometry to stochastic field theories [34].

Finally, inspired by recent experimental works on bacterial colonies, we have here focused on the self organization of run-and-tumble particles interacting via QS. Our results can however be straightforwardly extended to other classes of active particles, such as Active Brownian particles or AOUPs, using established methods [38, 39]. They should also be generalizable to chemotactic interactions, which lead to fluctuating hydrodynamics akin to that emerging from QS interactions [33].
In the context of bacterial colonies, motility-induced patterns will eventually interact with population dynamics [18, 20, 27] and genetics [42]. How this interplay will result in diverse coexisting communities is a fascinating research direction for the future indeed.
