ABSTRACT

In this work, we introduce DAMNETS, a deep generative model for Markovian network time series. Time series of networks are found in many fields such as trade or payment networks in economics, contact networks in epidemiology or social media posts over time. Generative models of such data are useful for Monte-Carlo estimation and data set expansion, which is of interest for both data privacy and model fitting. Using recent ideas from the Graph Neural Network (GNN) literature, we introduce a novel GNN encoder-decoder structure in which an encoder GNN learns a latent representation of the input graph, and a decoder GNN uses this representation to simulate the network dynamics. We show using synthetic data sets that DAMNETS can replicate features of network topology across time observed in the real world, such as changing community structure and preferential attachment. DAMNETS outperforms competing methods on all of our measures of sample quality over several real and synthetic data sets.

1 Introduction

Graphs, or networks, are mathematical objects (with nodes and edges as building blocks) that have gained tremendous popularity in the last decades, due to their usefulness in representing network connectivity structure of real data. Their application spans a large number of fields ranging from biology to engineering and finance. An excellent introduction can be found in Newman [2018]. The last few years have seen a surge of interest in methods for generating synthetic data, driven by the need of large scale data for training machine learning algorithms, and also to alleviate privacy concerns in certain data-sensitive applications, see for example Rodriguez and Howe [2019].

Although there is a large existing literature on generating static networks (i.e., networks that do not evolve over time), generating time series of networks has received relatively little attention. While networks are often used to represent complex dependencies, network time series represent complex dependencies also across time. The task here is to generate synthetic data which replicate the dependencies that are relevant for the research question. As an example, in a time series of social contact networks, the interest may lie in replicating not only the degree distribution but also the clustering behaviour, to capture the interplay between these summary statistics over different times of the day. This complexity is further exacerbated due to the high dimensional nature of network time series, a single network time

*Corresponding author
series of length $T$ on $n$ nodes being of size $T \times n^2$. When there are $N$ time series in the data set, for example weekly time series with $N$ the number of weeks, this results in a data set of size $N \times T \times n^2$. Building a generative model that faithfully replicates both network topology and sequential dependence between graph snapshots is an extremely challenging task.

Data-driven generative models of other types of sequential data, such as natural language, commonly follow an encoder-decoder structure, e.g. Sequence2Sequence [Bahdanau et al., 2015] and Transformer [Vaswani et al., 2017] models. These models compute a latent representation of the input sequence, then recurrently decode these latent variables into sampled output. Due to the sequential nature, latent states for a given token are usually computed as some function of the tokens close-by in the sequential ordering. With graph data we can use a similar approach, however we must also consider the meaningful connectivity structure provided by the adjacency matrix of the graph; a good generative model should leverage this information to produce high quality samples.

To address this challenge, Graph neural networks (GNNs) are a natural choice. GNNs have seen an explosion in popularity amongst the machine learning community in recent years (for a review see Zhou et al. [2020b]), achieving state-of-the-art performance across a variety of tasks. GNNs explicitly use graph connectivity to compute an embedding for each node, which is then utilised downstream for a variety of tasks, including link prediction and graph classification. Graph neural networks form the basis of the GRAN model [Liao et al., 2019] for static network generation, which was shown to outperform both Recurrent Neural Networks (RNN) and Variational autoencoders (VAE) based methods.

In this work, we propose DAMNETS, a GNN encoder-decoder model for generating samples from a Markov chain on the space of networks. We use an encoder GNN to learn embeddings for the input graph, which are passed to an autoregressive GNN decoder that generates the subsequent network one node at a time, in a recurrent manner. Further, unlike other methods, DAMNETS is able to learn from one long observation of a network time series or multiple shorter realisations of a time series.

**Main contributions.** (1) DAMNETS is the first GNN model for generating synthetic network time series which is able to faithfully reproduce not only degree distributions but also clustering behaviour in network time series. (2) This feat is achieved through a novel architecture which is efficient yet takes graph structure into account. This architecture may be of independent interest. (3) The behaviour of DAMNETS is illustrated in two synthetic settings, one of which may be used as a new benchmark setting. DAMNETS is also applied to two real-world network time series, illustrating its ability to capture topological network features.

**Notation.** In this paper, we shall restrict our attention to time series of simple, undirected, labelled graphs on a fixed node set. A graph is defined as $G = (V, E)$ where $V = \{1, \ldots, n\}$ is the node set, and $E \subset \{(i, j) : i, j \in V\}$. A graph $G$ emits an adjacency matrix $A \in \mathbb{R}^{n \times n}$ defined as $A_{ij} := 1$ if $(i, j) \in E$. We consider observed sequences of labelled time series of graphs $G_0, G_1, \ldots, G_T$, over a fixed node set $V = \{1, \ldots, n\}$. An element of the sequence $G_t$ has representation $G_t = (V, E_t)$ where $E_t \sim p_t (V \times V)$, a time-dependent probability distribution over the potential edges on $V$, and emits adjacency matrix $A^{(t)}$.

**Paper outline.** The remainder of this paper is structured as follows. Section 2 is a brief summary of related work from the rather sparse literature on network time series generation. Section 3 introduces the algorithmic pipeline we propose for the task at hand. Section 4 details the outputs of numerical experiments for both representative generative models from the network literature, and also real world networks. Finally Section 5 summarises our main findings and proposes future avenues of investigation.

## 2 Related Work

### 2.1 Static Network Generation

The generation of networks is a classical topic in graph theory known as Random Graphs, including the famous Erdős-Rényi model [Erdős and Rényi, 1959], the simplest possible random graph. Other statistical models were designed to capture specific characteristics of networks such as the Barabási-Albert model [Albert and Barabasi, 2001] for power-law degree distributions and stochastic block models [Holland et al., 1983] for community structure.

These models bear the advantage of being simple to construct and fully probabilistic. However, the network features that they can replicate is fixed a-priori, rendering them not flexible enough to model arbitrary network data often encountered in real world applications, which exhibit intricate/complex inter-dependencies between edges. Recently, several machine learning approaches have shown good performance on generating arbitrary sets of networks, including DeepGMG [Li et al., 2018], GraphRNN [You et al., 2018] and GRAN [Liao et al., 2019]. Our paper continues this progression to the network time series setting.
2.2 Network Time Series (NTS) Generation

In the static setting, there are classical models for generating time series of networks designed to capture a specific set of NTS characteristics, such as the *forest fire* process [Leskovec et al., 2005], which can produce power-law degree distributions and shrinking effective diameter (i.e., the length of a largest shortest path in the graph).

Approaches attempting to generate arbitrary network time series have appeared in the machine learning literature, such as the TagGen model [Zhou et al., 2020a], which uses a self-attention mechanism to learn from temporal random walks on a network time series, from which new network time series are subsequently generated. Another very recent algorithm is DYMOND [Zeno et al., 2021], which is a simpler approach that models the arrival times of 3-node motifs, then samples these subgraphs to generate the NTS. It is important to note that both DYMOND and TagGen attempt to solve a slightly different problem; they take as input a single time series \(G_0, \ldots, G_T\), and aim to generate an entire time series with the same network statistics. DAMNETS assumes the NTS in question is Markovian, and generates one transition of the network dynamics at a time. As a result of this, DAMNETS can learn from multiple realisations of a time series.

The approach most similar to our own is the Attention-Based Graph Evolution (AGE) model [Fan and Huang, 2020]. AGE uses a model very similar to a Transformer [Vaswani et al., 2017], where a self-attention mechanism is applied to the rows of \(A^{(t-1)}\) to learn node embeddings, and a source target attention module is sequentially applied to generate the rows of \(A^{(t)}\). AGE has two clear shortcomings; the first one is that it does not explicitly account for graph connectivity, which is left to the attention mechanism to deduce. The second is that it does not capture edge-level correlations on the sampled rows. To give a trivial example of why this is important, suppose we were considering a network time series where in every graph snapshot, each node has exactly two neighbours; the model should have some mechanism to condition on the edges it has sampled for a node so that it can stop once it has generated two edges. DAMNETS explicitly utilises graph connectivity in the model pipeline and has the capacity to model edge correlations within rows of the adjacency matrix.

3 Model

![Figure 1: An overview of the DAMNETS model architecture. An encoder GNN computes node embeddings for the input graph \(G_{t-1}\), which are then updated by the decoder GNN as new edges are sampled. The new and old node embeddings are compared to produce edge probabilities, which are then sampled.]

To generate Markovian network time series, it is sufficient to approximate and produce samples from \(\tilde{G}_t \sim p(\cdot | G_{t-1})\), where \(G_{t-1}\) and \(\tilde{G}_t\) are simple labelled graphs on \(n\) nodes. As described above, inspired by the sequential generation, we shall use an encoder-decoder model, adjusting for the dependencies inherent in the graph structure. An overview of our pipeline and model architecture is depicted in Figure 1.

The first step is to compute node embeddings for \(G_{t-1}\), using a GNN. We employ a Graph Attention Network (GAT) [Veličković et al., 2018], although any GNN layer is applicable. Given node features \(X_1, \ldots, X_n, X_i \in \mathbb{R}^F\), a GAT
layer produces a new set of node features \( h_i \in \mathbb{R}^{F'} \) according to
\[
    h_i = \sigma \left( \sum_{j \in N_i} \alpha_{ij} WX_j \right).
\]
(1)

Here \( W \in \mathbb{R}^{F' \times F} \) is a learnable weight matrix, \( \sigma(\cdot) \) is a non-linear function applied element-wise, and \( \alpha_{ij} \in \mathbb{R} \) are normalised attention coefficients computed as
\[
    e_{ij} = a(WX_i || WX_j),
\]
(2)
\[
    \alpha_{ij} = \frac{\exp(e_{ij})}{\sum_{k \in N_i} \exp(e_{ik})},
\]
(3)

where \( || \) represents the concatenation operation, and \( a(\cdot) \) is a single layer MLP with the LeakyReLU activation function. These layers are stacked to produce a GAT network. GAT layers can also employ multi-head attention [Vaswani et al., 2017]. We write \( GAT(X, A) \) to represent the application of a GAT network to a graph with node feature matrix \( X \) and adjacency matrix \( A \).

We consider only labelled, simple networks in this work, and use the identity matrix as node features. Node or edge-level features, whenever available, can be incorporated into the pipeline. The embedding of \( G_{t-1} \) is given by
\[
    H^{(t-1)} = GAT_{enc}(I, A^{(t-1)}),
\]
(4)
where \( I \in \mathbb{R}^{n \times n} \) is the identity matrix, and \( H^{(t-1)} \in \mathbb{R}^{n \times F} \) is the node embedding matrix.

The embeddings \( h_i^{(t-1)} \) are then used by the recursive GNN decoder to generate \( G_t \) one node at a time. When adding the \( i \)th node, we compute node embeddings for the already sampled \( i - 1 \) node subgraph \( G_{t\{1,...,i-1\}} \) (with adjacency matrix \( A^{(t)}_{i\{1,...,i-1\}} \)) as
\[
    H_i^{(t)} = GAT_{dec}(H^{(t-1)}_i, A^{(t)}_{i\{1,...,i-1\}}),
\]
(5)
where \( A^{(t)}_{i\{1,...,i-1\}} \) is the adjacency matrix corresponding to \( G_{t\{1,...,i-1\}} \). The next step is to sample the edges between node \( i \) and \( G_{t\{1,...,i-1\}} \), which is equivalent to sampling the \( i \)th row of the adjacency matrix. The likelihood of the row \( A^{(t)}_i \in \mathbb{R}^{1 \times 1} \) is given by the following dependent mixture of Bernoulli distribution
\[
    p(A^{(t)}_i | H_i^{(t)}, G_{t-1}) = \sum_{k=1}^{K} \alpha_k \prod_{1 \leq j < i} \theta_{k, i, j} A^{(t)}_{i, j}(1 - \theta_{k, i, j})^{1 - A^{(t)}_{i, j}}
\]
(6)
where
\[
    \alpha_1, \ldots, \alpha_K = \text{Softmax} \left( \sum_{1 \leq j < i} f_{\alpha}(h^{(t-1)}_i - h^{(t)}_j) \right),
\]
(7)
\[
    \theta_{1, i, j}, \ldots, \theta_{K, i, j} = \sigma (A^{(t-1)}_{i, j} f_1(h^{(t-1)}_i - h^{(t)}_j) + (1 - A^{(t-1)}_{i, j}) f_2(h^{(t-1)}_i - h^{(t)}_j)).
\]
(8)

Here \( f_{\alpha}, f_1, f_2 : \mathbb{R}^H \rightarrow \mathbb{R}^K \) are MLPs with ReLU activation functions, \( \sigma(\cdot) \) is the logistic sigmoid function (applied element-wise) and \( K \) is the number of mixture components. This is a modification of the dependent mixture of Bernoulli likelihood introduced in Liao et al. [2019], which allows for (a weak form of) edge-conditional sampling in \( O(1) \) generation steps.

Intuitively, the model produces \( K \) choices for the edge probabilities of the row (which are treated as independent Bernoulli random variables), but the choice of mixture component \( \alpha_k \) allows the model to select the best distribution based on the specific realisation of \( G_{t\{1,...,i-1\}} \) that has been sampled. The edge probability for an edge \((i, j)\), where \( i < j \) is computed as a function of the difference between \( h^{(t-1)}_i \), the embedding in \( G_{t-1} \) for the node \( i \) currently being added (i.e. the most "up to date" information we have about that node), and \( h^{(t)}_j \), which reflects the updated role of node \( j \) in \( G_{t\{1,...,i-1\}} \). The functions \( f_1 \) and \( f_2 \) allow the model to distinguish between the addition and removal of edges. The model samples each row of the adjacency this way until all \( n \) nodes have been added.
4 Numerical Experiments

In this section, we validate the efficacy of DAMNETS on a number of synthetic and real NTS data sets. The synthetic data sets are constructed to demonstrate the capacity of our model to capture network properties widely observed in empirical data, namely community structure and power-law degree distributions. We compare the samples produced by our model to samples from three baseline models, namely the AGE (Attention-Based Graph Evolution) [Fan and Huang, 2020], DYMOND (DYnamic MOtif-NoDes Network Generative Model) [Zeno et al., 2021] and TagGen [Zhou et al., 2020a] models. Note that both TagGen and DYMOND are only designed to produce samples from one observation of a network time series rather than learn a distribution over many trajectories; we therefore train these models separately on each observation in the test set, then produce a sample and aggregate the outputs - a simpler task as they have access to the test dataset and thus do not have to generalise from the training dataset. The AGE model does not have publicly available code, and thus we use our own implementation; for TagGen\(^2\) and DYMOND\(^3\), we use implementations provided by their authors, along with the default parameters, across all experiments. Code for our model can be found at https://github.com/DAMNETS/DAMNETS_ICML_2022.

4.1 Model Training and Hyper-Parameters

DAMNETS is trained by maximising the likelihood given in equation (6) of the training data using stochastic gradient descent. Model selection is done using a validation set. We use the Adam [Kingma and Ba, 2015] optimiser with learning rate $\ell = 3 \times 10^{-4}$.

During training, we found it beneficial to smooth the previous edge indicators $A_{ij}^{(t-1)}$ in Equation (8), instead using $\hat{A}_{ij}^{(t-1)} = (1 - \alpha)A_{ij}^{(t-1)} + \frac{\alpha}{2}$ for some small positive constant $\alpha$. This can be seen as a regularisation technique to prevent over-fitting on specific edges in the training set. We used $\alpha = 0.1$ for all the experiments in this paper. We also apply dropout at all layers of the model pipeline, using a dropout probability $p_{drop} = 0.2$.

For all experiments that follow we set the model hidden size $H = 256$ and use 2-layer GAT networks for the encoder and decoder. We use 3 layer MLPs for $f_\alpha, f_1, f_2$ with ReLU activation functions, and we keep the number of mixture components fixed at $K = 20$.

![Figure 2: A sample from the community decay model of length $T = 5$ on $V = \{1, \ldots, 45\}$, with 15 nodes in each of the $Q = 3$ communities, connection probabilities $p_{int} = 0.7, p_{ext} = 0.005$, decay community $D = 3$ and decay fraction $f_{dec} = 0.2$. The nodes in the decaying (third) community are coloured red.](https://github.com/davidchouzdw/TagGen)

4.2 Comparing NTS Generators

Comparing distributions over networks is in general a difficult problem due to the high-dimensional sample space (on $n$ nodes there are $O(2^{n^2})$ possible edge configurations). In the static network setting, it is common to instead compare the distributions of a set of mainstream summary statistics computed over a set of networks, such as the density, clustering coefficient or motif counts; this approach was employed in the GraphRNN [You et al., 2018] and GRAN [Liao et al., 2019] lines of work, where the Maximum Mean Discrepancy [Gretton et al., 2012] between the sampled and test set networks was computed as a measure of performance.

Comparing distributions over time series of networks is even more difficult. Our synthetic datasets were chosen such that there is an obvious sufficient statistic for the underlying data generating process that we can test against, but for the real data we simply inspect the results visually.

\(^2\)https://github.com/davidchouzdw/TagGen

\(^3\)https://github.com/zenol29/DYMOND
4.3 Community Evolution and Decay

Our first network time series benchmark is based on a stochastic block model initial structure - a standard generative graph model defined as follows. The initial network \( G_0 = (V, E_0) \) with node set \( V = \{1, \ldots, n\} \) is equipped with a surjective community membership function \( C : \{1, \ldots, n\} \rightarrow \{1, \ldots, Q\} \) that encodes which of the \( Q \) communities a given node \( i \) belongs to (a node can only belong to one community). The initial graph \( G_0 \) is then fully described by the interior (within community) and exterior (across communities) edge probabilities \( p_{ij} := P((i, j) \in E_0) \), given by

\[
p_{ij} = \begin{cases} p_{int} & \text{if } C(i) = C(j) \\ p_{ext} & \text{if } C(i) \neq C(j). \end{cases}
\]

A network time series \( G_1, \ldots, G_T \) is then constructed as follows; we fix a community \( D \in \{1, \ldots, Q\} \) that we denote the decay community. We define the set of internal edges for community \( D \) as

\[
D_t^{int} := \{(i, j) \in E_t | C(i) = C(j) = D\}.
\]

At each iteration \( t \), (i.e time step), a fixed proportion \( f_{\text{dec}} \) of the internal edges \( D_t^{int} \) are replaced with external edges. This is achieved by selecting a random internal edge \((i, j)\) and removing it from the edge set \( E_t \), then selecting a node \( u \) uniformly from \( \{i, j\} \). We then select a random endpoint \( k \) uniformly from \( \{v \in V | C(v) \neq D, (u, v) \notin E_t\} \), the set of nodes not in community \( D \) and not connected to \( u \), and finally add the edge \((u, k)\) to the edge set \( E_t \). We repeat this procedure \( T \) times to generate our network time series.

The model can be interpreted as starting with a network with \( Q \) densely connected communities, decaying in time to have only \( Q - 1 \) clear communities; the decay community \( D \) will appear as noise around those left unperturbed. A sample from the model can be seen in Figure 2; for ease of visualisation, each initial community has only 15 nodes.

Notice the community model is Markovian. It is also easy to gauge whether the output distribution of a given generative model trained on samples from the community decay model is correct, as we may simply compare the densities of the three communities in time; the non-decay communities should have constant density, and the decay community should have density decaying exponentially at rate \( f_{\text{dec}} \).

The experimental setup is as follows. We draw 150 network time series from the community decay model to act as training data, and another 150 as test data. Here, we choose \( Q = 3 \) communities, with community \( D = 3 \) the one which is decaying. Each initial community has 200 nodes, so that there are \( n = 600 \) nodes in total. We train the models and then sample 150 output network time series from the trained generative models, and compare the density distributions of the different communities between output and test samples to evaluate the fit. The parameters used for the community decay experiment are displayed in the supplementary material (see Table 2).

Figure 3 shows the density of the three communities evolving in time. DAMNETS is able to accurately represent the decaying community structure with good accuracy, while keeping the other two fixed, while the baseline models are unable to model this time-evolving structural change.

Figure 4 shows a comparison in terms of a set of generic network statistics computed through time, namely the number of edges, average clustering coefficient and the transitivity (also known as the global clustering coefficient), where transitivity is defined as \( \frac{3 \times \# \text{triangles}}{\# \text{triads}} \); for background on network statistics see, for example, Newman (2018). At each time-step, we calculate the value of each statistic for all sampled and test networks, then take the average of these statistics. Our model output distributions match the test set well on all three statistics.

Figure 3: The mean density in time of the different communities sampled from the sampled and test data sets. Standard deviations of the community densities of the sampled network time series are given by the shaded regions.
Figure 4: Average statistics computed throughout time for the network time series sampled from the each model and those from the test set (true samples from the 3-community decay model).

Figure 5: A density estimation of the degree distributions of the final network $G_T$ in both the test and sampled B-A networks. We see that DAMNETS is visually the closest fit, in particular matching the power law tail well.

4.4 The Barabási–Albert Model

The family of Barabási–Albert (B-A) models [Albert and Barabási, 2001] was designed to capture the so-called scale-free property observed in many real world networks through the preferential attachment mechanism. Formally a scale-free network is one whose degree distribution follows a power-law; if $\deg(i)$ represents the degree of node $i$ in a random network model, then the network is scale free if

$$P(\deg(i) = d) \propto \frac{1}{d^\gamma},$$

for some constant $\gamma \in \mathbb{R}$. Degree distributions with a power-law tail have been observed in many real networks of interest, such as hyperlinks on the World-Wide Web or metabolic networks, although the ubiquity of power law degree distributions has been disputed [Clauset et al., 2009].

The B-A model has two integer parameters, the number of nodes $n$ and the number of edges $m$ to be added at each iteration. The network is initialised with $m$ initial connected nodes. At each iteration $t$, a new node is added and is connected to $m$ existing nodes, with probability proportional to the number of edges incident to the existing nodes. Here, the standard NetworkX [Hagberg et al., 2008] implementation is used. The probability that a new node is connected to a node $u \in V$, $p_u$, is directly proportional to its degree

$$p_u = \frac{\deg(u)}{\sum_{v \in V} \deg(v)}.$$  

Constructing a B-A network in this way yields a network time series of length $T = n - m$, where each graph $G_t$ is the graph after node $m + t$ has the first edges attached to it. Notice that nodes with a large number of existing connections (known as hubs) will likely accumulate more links; this is the preferential attachment property which, in the case of the B-A model, leads to a power-law degree distribution with scale parameter $\gamma = 3$.

We test the model in a similar fashion to the community decay model; we sample 300 networks from the B-A model to function as a training set, and another 300 as a test set. We then sample 300 output networks from the synthetic data.
models and compare the relevant network statistics. The parameters $n = 50$, $m = 4$ were used for the B-A model. We aggregate the construction of the B-A networks: each time 5 nodes are added, giving time series of length $T = 10$.

Figure 5 shows the degree distribution of the final network $G_T$ in the sampled and test B-A network time series. We observe that the density of the model output networks closely matches the test set density; in particular, our model is able to re-create the power-law degree distribution of the B-A model. We also perform two sample Kolmogorov-Smirnov tests between the degree distribution of the final networks in the test set and those generated by the models; the results can be seen in Table 1. For the NTS sampled from TagGen and DYMOND, we can safely reject the null hypothesis that the degree distributions are the same at the 5% level, but we cannot do so for the DAMNETS samples.

Table 1: Two sample K-S tests between the degree distribution of the final network $G_T$ in the test set and those produced by the models in comparison. We are able to reject the null hypothesis that the degree distributions are the same for the test and sampled networks safely at the 5% level for AGE, TagGen and DYMOND, but cannot reject the null for the samples from DAMNETS.

Figure 6 shows a comparison of the output and test distributions of our chosen network statistics. Visually, our model provides a good fit on all three statistics.

4.5 Real Data

Next we illustrate DAMNETS on two real data sets. The first data set is a proximity network from the Copenhagen Networks Study [Sapiezynski et al., 2019]. The data represents physical contacts between a population of over 700 university students, observed temporally over a period of four weeks. The data were collected via smartphones and here we refer to it as bluetooth data set. One of the interesting features of this data set is the temporal variation in network density, coupled with variation in types of interactions, see also Stopczynski et al. [2014]. We partition the data into $N = 4$ weekly time series, and we partition each week into 14 network snapshots (each representing half a day), so we have length $T = 14$ time series. DAMNETS requires a fixed node set, so we only consider nodes present at the first timestep, giving networks of size $n = 517$. This data set is periodic (see Figure 9 in the supplementary material) and non-Markovian; to alleviate this issue, we concatenate a one-hot temporal embedding to the initial node features of the encoder indicating the offset within the period. We train on the first three weeks of data and evaluate using the final week.

Figure 7 shows the results and confirms that DAMNETS is not only able to capture the density over time, but also gives good fits to average clustering and transitivity. Thus, DAMNETS output could be used to create a synthetic network time series which preserves main features of the data set but allows for privacy by not revealing the underlying data set. We omit DYMOND and TagGen from the plot as they obscure the periodic structure, but we include this in the supplementary material for completeness (see Figure 10).

The second data set consists of financial correlation networks built from time series of asset prices. Again there is no clear sufficient statistic to examine for this dataset, so we simply provide a summary of the network statistics over time. Figure 8 shows the average network statistics for this dataset.
DAMNETS: A Deep Autoregressive Model for Generating Markovian Network Time Series

Figure 7: The network statistics from the bluetooth data experiment. The black line shows the network statistics computed over the week held out as test data, and the blue line shows the sampled network time series from DAMNETS, capturing the periodic structure quite well.

Figure 8: Average network statistics computed throughout time for the Correlation dataset. The shaded regions indicate one standard deviation. DAMNETS is considerably closer to the true values in the test data (labelled Test) than TagGen or DYMOND.

The AGE method performed very poorly on these data sets, hence is omitted from the plots for clarity. DAMNETS fits both these data sets well on all three statistics.

5 Conclusion and Outlook

Generating synthetic network time series is in its infancy. Yet, synthetic network time series could be useful for modelling and software development if they replicate features which are of importance in the underlying network time series. DAMNETS is a novel GNN structure which is able to generate synthetic networks that can replicate topological features of networks over time, to a much higher standard than previous methods.

This paper is kept as simple as possible to make the ideas behind DAMNETS transparent. There are many extensions which will be part of future work. To name but a few, including edge weights and signed edges is fairly straightforward. Exogeneous features for edges and nodes could be included. Moreover, the underlying Markov chain could be allowed to switch regime, thus allowing for change-point detection and for more involved modelling.

Synthetic but faithful network time series could play a major role in privacy-preserving problems, such as analysis of health records or of financial transaction data. Pursuing these applications will also be part of future research.

In addition, it would be interesting to evaluate our generative model on other global structure properties of the graph, such as shortest path distances, betweenness centrality, and more broadly, approximately matching the Laplacian spectrum, that is known to capture global structure and graph connectivity information, in the spirit of the recent work in Shine and Kempe [2019].
