We weaken the notion of “not subject to occur-check” (NSTO), on which most known results on
avoiding the occur-check in logic programming are based. NSTO means that unification is performed
only on such pairs of atoms for which the occur-check never succeeds in any run of a nondeterministic
unification algorithm. Here we show that “any run” can be weakened to “some run”. We present
some related sufficient conditions under which the occur-check may be safely omitted. We show
examples for which the proposed approach provides more general results than the approaches based
on well-moded and nicely moded programs (this includes cases to which the latter approaches are
inapplicable). We additionally present a sufficient condition based on NSTO, working for arbitrary
selection rules.

Keywords: occur-check, unification, modes, delays

1 Introduction

The programming language Prolog implements SLD-resolution employing an unsound implementation
of unification without the occur-check. This usually creates no problems in practice. Programmers know
that they do not need to care about it, unless they deal with something unusual like checking a difference
list for emptiness\(^1\). Surprisingly, such attitude of programmers is often not justified by theory. The
known criteria for occur-check freeness are applicable to restricted classes of cases. There seems to exist
no further substantial work on avoiding the occur-check after that of Chadha and Plaisted [CP94], Apt
and Pellegrini [AP94], reported in [Apt97], and the generalization in [AL95] to other selection rules than
that of Prolog.

Even for LD-resolution (SLD-resolution with the Prolog selection rule) the proposed methods are
inapplicable to some important cases. To deal with simple examples of programs employing difference
lists, the methods of well-moded and nicely moded programs had to be refined [AP94] in a rather so-
phisticated way. (The refinement is not presented in the textbook [Apt97], one may suppose that it was
considered too complicated.)

The existing approaches are based on the notion of NSTO (not subject to occur-check) [DFT91]. It
means that unification is performed only on such pairs of atoms for which the occur-check never succeeds
in any run of a nondeterministic unification algorithm.

It turns out that unification without the occur-check works correctly also for some cases which are not
NSTO. In this paper we propose a generalization of NSTO (Section\(^3\)). We show that it is sufficient that
the occur-check does not succeed in one run of the unification algorithm for a given input, instead of all

\(^1\)In the important Prolog textbook by Sterling and Shapiro [SS94], the occur-check is mentioned (in the context of ac-
tual programs) only when discussing difference lists (p. 298, p. 300, on p. 299 an error due to unsound Prolog unification is
explained). The textbook of Bratko [Bra12] mentions the occur-check only once, when comparing matching in Prolog with
unification in logic.
the runs (Section 3.2). We discuss some related sufficient conditions for safely avoiding the occur-check (Section 3.4). They are applicable to some examples to which the former approaches are inapplicable. For other examples, a wider class of initial queries is dealt with, or/and applying the proposed approach seems simpler than the former ones. We additionally present a sufficient condition, based on NSTO (Section 3.5), for safely avoiding the occur-check under arbitrary selection rule (and provide a detailed proof of its correctness). Approaches based on semantic analysis of programs, like abstract interpretation, are left outside of the scope of this work. This report is an extended version of [Dra21a].

Preliminaries

We use the terminology, notation and many definitions from [Apt97] (and reintroduce here only some of them). The terminology is based on that of logic; in particular “atom” means an atomic formula.

By an expression we mean a term, an atom, or a tuple of terms (or atoms). An equation is a construct \( s \vdash t \), where \( s, t \) are expressions. Given sequences of terms (or atoms) \( s = s_1, \ldots, s_n \) and \( t = t_1, \ldots, t_n \), the set \( \{ s_i \vdash t_i, \ldots, s_n \vdash t_n \} \) will be sometimes denoted by \( s \equiv t \). A syntactic object (expression, equation, substitution, etc) is linear when no variable occurs in it more than once. As in Prolog, each occurrence of \( _{-} \) in a syntactic object will stand for a distinct variable. Otherwise variable names begin with upper case letters. \( \text{Var}(t) \) denotes the set of variables occurring in a syntactic object \( t \). We say that \( s \) and \( t \) are variable disjoint if \( \text{Var}(s) \cap \text{Var}(t) = \emptyset \).

For a substitution \( \theta = \{ X_1/1, \ldots, X_n/n \} \), we define \( \text{Dom}(\theta) = \{ X_1, \ldots, X_n \} \), \( \text{Ran}(\theta) = \text{Var}(t_1, \ldots, t_n) \), \( \theta|S = \{ X/t \in \theta | X \in S \} \) (for a set \( S \) of variables), and \( \theta|u = \theta|\text{Var}(u) \) (for an expression \( u \)).

We employ the Martelli-Montanari unification algorithm (MMA) (cf. [Apt97]). It unifies a set of equations, by iteratively applying one of the actions below to an equation from the current set, until no action is applicable. The equation is chosen nondeterministically.

\[
\begin{align*}
(1) \; \; f(s_1, \ldots, s_n) & \equiv f(t_1, \ldots, t_n) & \rightarrow & \text{replace by equations } s_1 \equiv t_1, \ldots, s_n \equiv t_n \\
(2) \; \; f(s_1, \ldots, s_n) & \equiv g(t_1, \ldots, t_m) \text{ where } f \neq g & \rightarrow & \text{halt with failure} \\
(3) \; \; X \equiv X & \rightarrow & \text{delete the equation} \\
(4) \; \; t \equiv X \text{ where } t \text{ is not a variable} & \rightarrow & \text{replace by } X \equiv t \\
(5) \; \; X \equiv t \text{ where } X \notin \text{Var}(t) \text{ and } X \text{ occurs elsewhere} & \rightarrow & \text{apply substitution } \{ X/t \} \text{ to all other equations} \\
(6) \; \; X \equiv t \text{ where } X \in \text{Var}(t) \text{ and } X \neq t & \rightarrow & \text{halt with failure}
\end{align*}
\]

By a run of MMA for an input \( E \) we mean a maximal sequence \( E_0, \ldots, E_n \) of equation sets such that \( E = E_0 \) and \( E_i \) is obtained from \( E_{i-1} \) by one of the actions of the algorithm \( (i = 1, \ldots, n) \). See [Apt97] for the properties of MMA, in particular how the obtained mgu is represented by a final equation set. An equation set \( E \) is said to be NSTO if action (6) is not performed in any execution of MMA starting with \( E \). We often say “unification of \( s \) and \( t \) is NSTO” instead of “\( \{ s \equiv t \} \) is NSTO”. In such case while unifying \( s, t \) the occur check never succeeds, and thus can be skipped.

We need to generalize some definitions from [Apt97], in order not to be limited to LD-resolution. We will say that \textit{unification of } \( A \text{ and } H \text{ is available} \) in an SLD-derivation (or SLD-tree) for a program \( P \), if \( A \) is the selected atom in a query of the derivation (tree), and \( H \) is a standardized apart head of a clause from \( P \), such that \( A \) and \( H \) have the same predicate symbol. (A more formal phrasing is “equation set \{ A \equiv H \} \text{ is available}”. ) If all the unifications available in an SLD-derivation (SLD-tree) are NSTO then the derivation (tree) is \textit{occur-check free}. We say that a program \( P \) with a query \( Q \) is \textit{occur-check free} if, under a given selection rule, the SLD-tree for \( P \) with \( Q \) is occur-check free.
We refer a few times to results of [AP94] reported in [Apt97]; in such cases only a reference to [Apt97] may be given.

Similarly to [AP94], we will employ modes. This means dividing the argument positions of predicates into two groups, by assigning a function \( m_p: \{1, \ldots, n\} \rightarrow \{+,-\} \) (called a mode) to each predicate \( p \) of the considered program (where \( n \) is the arity of \( p \)). A program with a mode for each predicate is called a moded program, and the collection of modes is called moding. We follow the usual terminology, argument positions with + assigned are called input, and those with − are called output. We usually specify \( m_p \) by writing \( p(m_p(1), \ldots, m_p(n)) \). E.g. \( p(+,−) \) states that the first argument of \( p \) is input and the second one is output. Note that moding does not need to correspond to any intuitive notion of data flow.

We will write \( p(s;t) \) to represent an atom \( p(t_1, \ldots, t_n) \) and to state that \( s \) is the sequence of terms in its input positions, and \( t \) the sequence of terms in its output positions. An atom \( p(s;t) \) is input-output disjoint if \( \text{Var}(s) \cap \text{Var}(t) = \emptyset \). Let us define \( \text{VarIn}(p(s;t)) = \text{Var}(s), \text{VarOut}(p(s;t)) = \text{Var}(t) \). The input (resp. output) positions of a query \( Q \) are the input (output) positions of the atoms of \( Q \). A query (or an atom) \( Q \) is input linear (resp. output linear) if the sequence of the terms occurring in the input (output) positions of \( Q \) is linear. We will refer to the following results.

**Lemma 1**

1. Consider atoms \( A \) and \( H \). If they are variable disjoint, one of them is input-output disjoint, one of them is input linear, and the other is output linear then \( \{A \models H\} \) is NSTO [Apt97, Lemma 7.14].

2. Let \( s \) and \( t \) be sequences of terms, such that the lengths of \( s \) and \( t \) are the same. If \( \text{Var}(s) \cap \text{Var}(t) = \emptyset \) and \( s \) (or \( t \)) is linear then \( s \models t \) is NSTO. (This is a special case of [Apt97, Lemma 7.5]; note that a ground term is linear).

Obviously, \( p(s) \models p(t) \) is NSTO iff \( s \models t \) is NSTO. Based on Lemma 1, Apt and Pellegrini [AP94] introduced two sufficient conditions for occur-check freeness. One (well-moded programs [Apt97, Def. 7.8]) implies that the input positions of the atoms selected in LD-trees are ground. The other one (nicely-moded programs [Apt97, Def. 7.19]) implies that the selected atoms are output-linear.

2 NSTO and arbitrary selection rules

**2.1 Sufficient condition**

Here we propose a syntactic condition for occur-check freeness under arbitrary selection rules. We assume that the programs dealt with are moded.

**Definition 2** Let \( Q = A_1, \ldots, A_n \) be a query. We define a relation \( \rightarrow_Q \) on \( \{A_1, \ldots, A_n\} \). Let \( A_i \rightarrow_Q A_j \) when a variable occurs in an output position of \( A_i \) and an input position of \( A_j \).

Query \( Q \) is tidy if it is output linear and \( \rightarrow_Q \) is acyclic (\( A_i \not\rightarrow_Q^+ A_i \) for \( i = 1, \ldots, n \)).

Clause \( H \leftarrow Q \) is tidy if \( Q \) is tidy, and

- \( H \) is input linear.
- no variable from an input position of \( H \) occurs in an output position of \( Q \).

Note that each atom in a tidy query is input-output disjoint. Also, if a query \( Q \) is tidy then any permutation of \( Q \) is tidy too. A linear query is tidy under any moding. This is a basic property of tidy clauses and queries:
Apt and Pellegrini [AP94] suggest that the approaches based on well-modedness or nice modedness generalize this result for other selection rules, however a proof seems unavailable.

Luitjes [AL95] generalize this result for other selection rules, however a proof seems unavailable.\footnote{[AL95] generalizes two results of [AP94], that for well moded and that for nicely moded programs. The monograph [Apt97] presents the first generalization, That related to Corollary 4, is for unknown reasons not even mentioned in “Bibliographic Remarks” [Apt97] p. 203]. For its proof, the reader of [AL95] is referred to an apparently unavailable master’s thesis. So Corollary 4 with its proof seems worth considering, despite it may be viewed as close to the result of [AL95].}

**Lemma 3** Let Q be a tidy query, and C a tidy clause variable disjoint from Q. An SLD-resolvent Q' of Q and C is tidy.

A proof is given in Appendix A. Now our sufficient condition for occur-check freeness is:

**Corollary 4** A tidy program with a tidy query is occur-check free, under any selection rule.

**Proof** By Lemma 3 in each SLD-derivation for a tidy program and query, each query is tidy. Assume A is an atom from a tidy query and H is the head of a standardized apart tidy clause. As A is input-output disjoint and output linear and H is input linear, \( \{A=tH\} \) is NSTO, by Lemma 1.

This result is a generalization of that for nicely moded programs [CP94], [AP94], [Apt97] (the first reference uses different terminology). The latter may be seen as Corollary 4 restricted to LD-resolution and to tidy programs/queries in which \( A_i \rightarrow Q A_j \) implies \( i < j \) (for each involved relation \( \rightarrow_Q \)). Apt and Luitjes [AL95] generalize this result for other selection rules, however a proof seems unavailable.\footnote{[AL95] generalizes two results of [AP94], that for well moded and that for nicely moded programs. The monograph [Apt97] presents the first generalization, That related to Corollary 4, is for unknown reasons not even mentioned in “Bibliographic Remarks” [Apt97] p. 203]. For its proof, the reader of [AL95] is referred to an apparently unavailable master’s thesis. So Corollary 4 with its proof seems worth considering, despite it may be viewed as close to the result of [AL95].}

### 2.2 Examples

Apt and Pellegrini [AP94] suggest that the approaches based on well-modedness or nice modedness are inapplicable to some programs, and introduced a more sophisticated approach. The programs are FLATTEN [SS94, Program 15.2], QUICKSORT\_DL [SS94, Program 15.4], and NORMALIZE [SS94, Program 15.7]; they employ difference lists. Here we focus on FLATTEN, which flattens a given list. (We split arguments of the form \( t \cup u \) or \( t++u \) into two argument positions; the argument positions of built-in predicates are considered input.)

\[
\text{FLATTEN:} \\
\% \text{flatten\_dll}(Xs,Ys,Zs) \rightarrow \text{difference list } Ys\setminus Zs \text{ represents the flattened list } Xs \\
\text{flatten\_dll}([X|Xs],Ys,Zs) \leftarrow \text{flatten\_dll}(X,Ys1,Zs). \\
\text{flatten\_dll}(X,[X|Xs],Ys) \leftarrow \text{constant}(X), X \setminus == []). \\
\text{flatten\_dll}([],Xs,Xs). \\
\text{flatten}(Xs,Ys) \leftarrow \text{flatten\_dll}(Xs,Ys,[]). \\
\]

We see that, for the program to be tidy, the second and the third arguments of \text{flatten\_dll} cannot be both output (\( Ys1 \) occurs in these positions in a clause body, which must be output linear). Also, the first and the second arguments of \text{flatten\_dll} cannot be both input, the same for the second and the third one (as a clause head must be input linear).

The reader is encouraged to check that \text{FLATTEN} is tidy under moding \( M_1 = \text{flatten}(+,-), \text{flatten\_dll}(+,-,+), \) and under \( M_2 = \text{flatten}(-,+), \text{flatten\_dll}(-,+,-) \). The relation \( \rightarrow_Q \) (where \( Q = A_1 \)) consists of one pair; for \( M_1 \) it is \( A_2 \rightarrow_Q A_1 \), for \( M_2 \) it is \( A_1 \rightarrow_Q A_2 \). In both cases the program remains tidy if the moding of \text{flatten} is replaced by \( (-,-) \).

For any term \( t \) and variable \( R \not\in \text{Var}(t) \), query \( Q_0 = \text{flatten}(t,R) \) is tidy under \( M_1 \). (To be tidy under \( M_2 \), \( Q_0 \) has to be linear.) By Corollary 4 \text{FLATTEN} with \( Q_0 \) is occur-check free, under any selection rule.

We only mention that \text{QUICKSORT\_DL} and \text{NORMALIZE} are also tidy, and thus are occur-check free for a wide class of queries. \text{NORMALIZE} is similar to \text{FLATTEN}, and is tidy for similar modings. \text{QUICKSORT\_DL} is tidy for instance for modings \text{quick\_sort(+,-)}, \text{quick\_sort\_dll(+,-,+),}
partition(+,+,−,−), and quicksort(−,+), quicksort_{dl}(−,+), partition(−,+,+,+). Another example of a tidy program is DERIVATIVE (Example 20 below).

Surprisingly, it is not noticed in [AP94] that the approach based on nice modedness is applicable to FLATTEN and NORMALIZE. FLATTEN is nicely moded under \( M_2 \), so is the query \( Q_0 \), provided it is linear. As the clause heads are input linear, it follows that FLATTEN with \( Q_0 \) is occur-check free for the Prolog selection rule (by [Apt97, Corollary 7.25]). Similarly, NORMALIZE is nicely moded (e.g. under \( \text{normalize}_{ds}(−,+) \)); we skip further details. In both cases the modes may be seen as not natural; what is understood as input data appears in a position moded as output. This may explain why the nice modedness of the programs was missed in [AP94].

3 Weakening NSTO

The discussion on avoiding the occur-check in all the referred work and in the previous section is based on the notion of NSTO. We show that NSTO is a too strong requirement. Unification without the occur-check produces correct results also for some pairs of atoms which are not NSTO. In such cases the algorithm may temporarily construct infinite terms, but eventually halt with failure. An example of such pair is \( p(a,f(X),X), p(b,Y,Y) \). For this pair, some runs of MMA halt due to selecting \( a \models b \), some other ones due to a successful occur-check. Omitting the occur-check would result in failure on \( a \models b \); this is a correct result.

NSTO requires that each run of MMA does not perform action (6). In this section we show that it is sufficient that there exists such run. For this we need to introduce a precise description of the algorithm without the occur-check, called MMA\(^-\). We define WNSTO, a weaker version of NSTO, and show that MMA\(^-\) produces correct results for expression pairs that are WNSTO. Then we show an example of a program with a query which is not occur-check free, but will be correctly executed without the occur-check, as all the atom pairs to be unified are WNSTO. Then we present sufficient conditions for safely skipping the occur-check, based on WNSTO.

3.1 An algorithm without the occur-check

By abuse of terminology, we will write “unification algorithm without the occur-check”, despite such algorithm does not correctly implement unification. We would not consider any actual unification algorithm of Prolog, this would require to deal with too many low level details. See for instance the algorithm of [Apt91, Section 2]. Instead, we use a more abstract algorithm, obtained from MMA. We cannot simply drop the occur-check from MMA (by removing action (6) and the condition \( X \notin \text{Var}(t) \) in action (5)). The resulted algorithm may not terminate, as an equation \( X \models t \) where \( X \in \text{Var}(t) \) can be selected infinitely many times.

We obtain a reasonable algorithm in two steps. Before dropping the occur-check, MMA is made closer to actual unification algorithms. The idea is to abandon action (5), except for \( t \) being a variable. (This action applies \( \{X/t\} \) to all equations except one.) Instead, when \( t \) is not a variable, \( \{X/t\} \) is applied only when needed, and only to one occurrence of \( X \). This happens when the variable becomes the left hand side of two equations \( X \models t, X \models u \) (where \( t,u \) are not variables, and \( X \notin \text{Var}(t,u) \)). Then \( X \models u \) is replaced by \( t \models u \). For technical reasons (termination), we require that \( t \) is not larger than \( u \).

Now, dropping the occur-check results in an algorithm presented by Colmerauer [Col82]. Without loss of generality we assume that we deal with unification of terms. Let \(|t|\) be the number of occurrences in \( t \) of variables and function symbols, including constants.
Definition 5 ([Col82]) MMA− (MMA without the occur-check) is obtained from MMA by

(a) removing action (6), and
(b) replacing action (5) by

\[ (5a) \ X \doteq Y, \text{ where } X, Y \text{ are distinct variables and } X \text{ occurs elsewhere} \]
\[ \rightarrow \ \text{apply substitution } \{ X/ Y \} \text{ to all other equations,} \]

\[ (5b) \ X \doteq t, \ X \doteq u \text{ where } t, u \text{ are distinct non-variable terms; let } \{ s_1, s_2 \} = \{ t, u \} \text{ and } |s_1| \leq |s_2| \]
\[ \rightarrow \ \text{replace } X \doteq s_2 \text{ by } s_1 \doteq s_2 \]

A set \( E \) of equations is in a semi-solved form if \( E \) is \( \{ X_1 \doteq t_1, \ldots, X_n \doteq t_n \} \), where \( X_1, \ldots, X_n \) are distinct, each \( X_i \) is distinct from \( t_i \), and if a \( t_i \) is a variable then \( X_i \) occurs only once in \( E \) (for \( i = 1, \ldots, n \)). \( E \) is in a solved form if, additionally, \( X_i \not\in \text{Var}(t_j) \) for \( 1 \leq i, j \leq n \).

Note that inability of performing any action of MMA− means that the equation set is in a semi-solved form.

Let us first discuss termination of MMA−. Let \( k > 1 \) be an integer greater than the arity of each function symbol appearing in the equation set \( E \) which is the input of the algorithm. We define a function \( ||| \) assigning natural numbers to equation sets and equations:

\[ ||| \{ t_1 \doteq u_1, \ldots, t_n \doteq u_n \} ||| = n \sum_{i=1}^{n} ||| t_i \doteq u_i |||, \quad \text{where} \quad ||| t \doteq u ||| = \max(|t|, |u|). \]

Assume that an action of MMA− is applied to a set \( E \) of equations, resulting in \( E' \). Then \( ||E|| = ||E'|| \) if the action is (4), (5a), or (5b), and \( ||E|| > ||E'|| \) if it is (3). By the lemma below, \( ||E|| > ||E'|| \) for action (1).

Lemma 6 For any terms (or atoms) \( s = f(s_1, \ldots, s_n) \), \( t = f(t_1, \ldots, t_n) \), \( ||s \doteq t|| > n \sum_{i=1}^{n} ||s_i \doteq t_i||. \)

Proof The inequality obviously holds for \( n = 0 \). Let \( n > 0 \), and \( l, r \) be, respectively, the left and the right hand side of the inequality. Without loss of generality, assume that \( |s| \geq |t| \). Now \( l = k \cdot k^{l_1} \cdots k^{l_n} \geq k \cdot k^{l_1} \cdots k^{l_n} \). Hence \( l/k \geq k^{l} \) for any \( u \in \{ s_1, \ldots, s_n, t_1, \ldots, t_n \} \). Thus \( l/k \geq ||s_i \doteq t_i|| \text{ for } i = 1, \ldots, n \), and then \( n \cdot l/k \geq r \). As \( n/k < 1 \), we obtain \( l > r \). □

Let \( f_{45a}(E) \) be the number of those equations from \( E \) to which action (4) or (5a) applies. Let \( f_{5b}(E) \) be the number of equations of the form \( X \doteq u \) in \( E \), where \( u \) is not a variable. Note that applying (4) or (5a) decreases \( f_{45a}(E) \), and applying (5b) decreases \( f_{5b}(E) \) without changing \( f_{45a}(E) \).

Now consider the lexicographic ordering \( \prec_3 \) on \( \mathbb{N}^3 \) (cf. for instance [Apt97], p. 33)]. If \( E' \) is obtained from \( E \) by applying one action of the algorithm, it holds that

\[ (||E'||, f_{45a}(E'), f_{5b}(E')) \prec_3 (||E||, f_{45a}(E), f_{5b}(E)). \]

Thus, as \( \prec_3 \) is well-founded, MMA− terminates for any input set of equations \( E \).

In discussing further properties of the algorithm, we will consider possibly infinite terms (i-terms) over the given alphabet. (See [Cou83] for a formal definition.) We require that the set of variables occurring in an i-term is finite. The corresponding generalization of the notion of substitution is called i-substitution.

\[ \text{Function } |||| \text{ is proposed and the lemma is stated without proof in [Col82]. There, however, } k \text{ is the maximal arity of symbols from } E, \text{ which does not make sense when it is 0 or 1. The lemma also holds (with a slightly longer proof) for } k \text{ being the maximal number out of 2 and the arities of the symbols.} \]
Definition 7 A substitution (respectively i-substitution) $\theta$ is a solution (i-solution) of an equation $t \equiv u$ if $t\theta = u\theta$: $\theta$ is a solution (i-solution) of a set $E$ of equations, if $\theta$ is a solution (i-solution) of each equation from $E$. Two sets of equations are equivalent (respectively i-equivalent) if they have the same set of solutions (i-solutions).

Lemma 8 If an action of MMA or of MMA$^-$ replaces an equation set $E$ by $E'$ then $E, E'$ are i-equivalent (and hence equivalent).

Proof For any i-substitution $\theta$, $f(s_1, \ldots, s_n)\theta = f(t_1, \ldots, t_n)\theta$ if $s_i = t_i$ for all $i \in \{1, \ldots, n\}$. Thus the claim holds for action (1). For actions (3), (4) the claim is obvious; for (2), (6) it is void. Actions (5) and (5a) replace an equation set $E = E_X \cup E_1$ by $E' = E_X \cup E_1 \{X \Rightarrow t\}$, where $E_X = \{X \Rightarrow t\}$. Consider an i-solution $\theta$ of $E_X$. So $X\theta = t\theta$. Hence $(V\{X/t\})\theta = V\theta$ for any variable $V$, and thus $t\{X/t\}\theta = t\theta$ for any expression $t$. So $\theta$ is a solution of $E_1$ iff $\theta$ is a solution of $E_1\{X/t\}$. For (5b), equivalence of $\{X \Rightarrow t, X \Rightarrow u\} \cup E_1$ and $\{X \Rightarrow t, t \Rightarrow u\} \cup E_1$ follows immediately from Def. [7]

Lemma 9 Any set of equations $E$ in a semi-solved form has an i-solution.

Proof If an equation of the form $X_i \Rightarrow Y$ occurs in $E$ then $E$ has an i-solution iff $E \setminus \{X_i \Rightarrow Y\}$ has an i-solution (as such $X_i$ occurs in $E$ only once). Hence we can assume that $E$ does not contain any equation of this form. Now the result follows from Th. 4.3.1 of [Cou83].

For a direct proof, consider $E = \{X_1 \Rightarrow t_1, \ldots, X_n \Rightarrow t_n\}$, where no $t_i$ is a variable. Let $\theta = \{X_1/t_1, \ldots, X_n/t_n\}$. Let $i \in \{1, \ldots, n\}$. Then $X_i\theta^{j+1} = t_i\theta^j$ for any $j \in \mathbb{N}$. Note that no variable from $\text{Dom}(\theta)$ occurs in $t_i\theta$ at depth $\leq j+1$ (by induction on $j$, as $\theta$ replaces each $X \in \text{Dom}(\theta)$ by a non-variable term). Hence $t_i\theta$ and $t_i\theta^{j+1}$ are identical at depths $\leq j + 1$. Let $u_i$ be the i-term which, for each $j \in \mathbb{N}$, is identical with $t_i\theta^j$ at depths $\leq j + 1$. Consider the i-substitution $\phi = \{X_1/u_1, \ldots, X_n/u_n\}$. Obviously, $X_i\phi$ is identical with $t_i\theta^j$ at depths $\leq j + 1$.

Note that $\theta^j = \{X_1/t_1 \theta^{j-1}, \ldots, X_n/t_n \theta^{j-1}\}$. So for each $i$, terms $X_i\theta^j$ and $X_i\phi$ are identical at depths $\leq j$. Hence $t_i\theta^j$ and $t_i\phi$ are identical at depths $\leq j + 1$. Also identical at depths $\leq j + 1$ are $X_i\phi$ and $t_i\theta^j$ (by the definition of $\phi$). Thus $X_i\phi$ and $t_i\phi$ are identical at such depths (for any $j \in \mathbb{N}$), hence $X_i\phi = t_i\phi$. So $\phi$ is an i-solution of $E$. 

In remains to discuss the results of MMA$^-$. Note that if $E$ and $E'$ are i-equivalent then they are equivalent. Consider a run $R$ of MMA$^-$ starting from an equation set $E$. If $R$ halts with failure (due to action (2)) then, by Lemma 8, $E$ has no solutions (is not unifiable). If it halts with equation set $E'$ in semi-solved form, then by Lemma 8, $E$ is unifiable iff $E'$ is. So applying MMA to $E'$, which boils down to applying actions (5) and (6), either halts with failure, or produces a solved form $E''$, representing an mgu of $E$. Prolog does not perform the occur-check, and treats the semi-solved form as the result of unification. Prolog implementations present the result to the user in various ways. For instance the answer to query $g(X, X) = g(Y, f(Y))$ is displayed as $X = Y, Y = f(Y)$ by SWI, and as $X = f(f(f(\ldots)))$, $Y = f(f(f(\ldots)))$ by SICStus (predicate =/2 is defined by clause =/(Z,Z)).

3.2 WNSTO

Let us say that a run of MMA is occur-check free if the run does not perform action (6). (In other words, no equation $X \Rightarrow t$ is selected where $X \in \text{Var}(t)$ and $X \neq t$; simply – the occur-check does not succeed.

---

4We say that a symbol $f$ occurs in a term $f(u_1, \ldots, u_k)$ ($k \geq 0$) at depth 1, and that $f$ occurs in $g(u_1, \ldots, u_k)$ at depth $j > 1$ if $f$ occurs in some $u_i$ ($1 \leq i \leq k$) at depth $j - 1$. E.g. $X$ occurs in $f(X, a)$ at depth 2.

We say that $f(u_1, \ldots, u_k)$ and $f(u'_1, \ldots, u'_k)$ ($k \geq 0$) are identical at depths $\leq 1$ and that $f(u_1, \ldots, u_k)$ and $f(u'_1, \ldots, u'_k)$ are identical at depths $\leq j$ (for a $j > 1$) provided that each $u_i$ and $u'_i$ are identical at depths $\leq j - 1$.
in the run). An equation set \( E \) is WNSTO (weakly NSTO) when there exists an occur-check free run of MMA for \( E \). When \( E \) is \( s \doteq t \) we also say that the unification of \( s \) and \( t \) is WNSTO. A program \( P \) with a query \( Q \) is weakly occur-check free if, under a given selection rule, all the unifications available in the SLD-tree for \( P \) with \( Q \) are WNSTO. A run of MMA on an equation set \( E \) is correct if it produces correct results i.e. the run halts with failure if \( E \) is not unifiable, and produces a unifiable equation set \( E' \) in a semi-solved form otherwise. The latter means that applying to \( E' \) action (5) iteratively produces an mgu of \( E \), in a form of an equation set in a solved form. We say that MMA is sound for \( E \) if all the runs of MMA on \( E \) are correct.

Now we show that if unification of \( E \) can be split in two parts and each of them is NSTO, then \( E \) is WNSTO. (For a proof see Appendix B.)

**Lemma 10** Let \( E_1 \cup E_2 \) be an equation set and \( E_1 \) be NSTO.

If \( E_1 \) is not unifiable then \( E_1 \cup E_2 \) is WNSTO.

If \( \theta_1 \) is an mgu of \( E_1 \), and \( E_2 \theta_1 \) is NSTO then \( E_1 \cup E_2 \) is WNSTO.

**Corollary 11** Consider a moding and atoms \( p(s;t) \) and \( p(s';t') \), where \( s \doteq s' \) is NSTO.

If \( s \doteq s' \) is not unifiable then \( p(s;t) \doteq p(s';t') \) is WNSTO.

If \( \theta \) is an mgu of \( s \doteq s' \), and \( (t \doteq t') \theta \) is NSTO then \( p(s;t) \doteq p(s';t') \) is WNSTO.

**Proof** Equation \( p(s;t) \doteq p(s';t') \) is WNSTO iff equation set \( s \doteq s' \cup t \doteq t' \) is WNSTO. Now Lemma 10 applies.

WNSTO is sufficient for the unification without the occur-check to work correctly:

**Theorem 12** Consider an equation set \( E \). Assume that there exists an occur-check free run of MMA on \( E \). Then MMA is sound for \( E \).

**Proof** Let \( R_1 \) be an occur-check free run of MMA on \( E \), and \( R_2 \) be a run of MMA on \( E \). We show that \( R_2 \) is correct. Let \( S \) be the set of the i-solutions of \( E \), and thus of every equation set \( E' \) appearing in \( R_1 \) or \( R_2 \) (by Lemma 8).

If \( R_1 \) succeeds then \( S \) contains unifiers of \( E \), and of every \( E' \) appearing in \( R_2 \). Hence action (2) is not performed in \( R_2 \), and \( R_2 \) halts with success producing a unifiable equation set \( E_2 \) in a semi-solved form.

If \( R_1 \) halts with failure then the last performed action is (2), thus \( S = \emptyset \). This implies that \( R_2 \) does not produce a semi-solved form (by Lemma 9). Hence \( R_2 \) terminates with failure, due to action (2).

It immediately follows that a weakly occur-check free program \( P \) with a query \( Q \) can be correctly executed without the occur check:

**Corollary 13** Assume a selection rule. If a program \( P \) with a query \( Q \) is weakly occur-check free then algorithm MMA is sound for each unification available in the SLD-tree for \( P \) with \( Q \).

### 3.3 Example – a weakly occur-check free program

The core fragment of the n queens program [Frü91] will be now used as an example. We call it NQUEENS, see [Dra22] for explanations.

\[
\begin{align*}
pqs(0,_,_,_). & \quad \text{(1)} \\
pqs(s(I),Cs,Us,[\_|Ds]):- & \\
opqs(I, Cs, [\_|Us], Ds), & \text{(2)} \\
opqs(s(I), Cs, Us, Ds). & \\
pq(I,[I\_], [I\_], [I\_]). & \quad \text{(3)} \\
pq(I,[\_|Cs], [\_|Us], [\_|Ds]):- & \\
pq(I, Cs, Us, Ds). & \quad \text{(4)}
\end{align*}
\]
The program works on non-ground data. A typical initial query is \( Q_{in} = pqs(n, q_0, _, _) \), where \( q_0 \) is a list of distinct variables, and \( n \) a natural number represented as \( s'(0) \).

We now show that the standard syntactic approaches to deal with avoiding the occur-check are inapplicable to NQUEENS. Under no moding the program is well-moded with \( Q_{in} \) because its answers are non-ground. To be tidy (or nicely moded with input linear clause heads), at most one position of \( pq \) is input (as (3) must be input linear). Thus at least three positions of \( pqs \) have to be output (as a variable from an input position of the head of (2) cannot appear in an output position of body atom \( pq(s(I), Cs, Us, Ds) \)). This makes the body not output linear, contradiction.

It can be shown that NQUEENS with \( Q_{in} \) is occur-check free under any selection rule, by showing that in all SLD-derivations each atom in each query is linear [Dra21b]. This is however rather tedious. The program is not occur-check free for some non linear queries, for instance for \( A_{STO} = pq(m, L, [L|\_], \_\_\_) \) (where \( m \) is ground). This is because unifying \( A_{STO} \) with the unit clause (3) is not NSTO.

We now show that NQUEENS can be correctly executed without the occur-check, for a wider class of initial queries. Let us say that a query \( Q \) is 1-ground if the first argument of the predicate symbol in each atom of \( Q \) is ground. We show that:

**Proposition 14** NQUEENS is weakly occur-check free, under any selection rule, for any 1-ground query.

**Proof** Note first that, in each SLD-derivation for NQUEENS and a 1-ground query, each query is 1-ground. Let \( A = p(s_1, \ldots, s_4) \) be a 1-ground atom, and \( H = pq(I, [I|\_], [I|\_], [I|\_]) \) be the head of (3), standardized apart. Equation \( s_1 \mapsto I \) is NSTO and \( \theta = \{I/s_1\} \) is its mgu. Let \( s = (s_2, s_3, s_4) \) and \( t = ([I|\_], [I|\_], [I|\_]) \). As \( s_1 \) is ground, \( t\theta \) is linear. Thus \( s\theta \mapsto t\theta \) is NSTO by Lemma 1. Hence by Lemma 10, \( s_1, s \mapsto I, t \) is WNSTO. So \( A \mapsto H \) is WNSTO. The cases of the remaining clause heads of NQUEENS are obvious, as the heads are linear. For another proofs, see Examples [17][19].

By Corollary 13 NQUEENS with any 1-ground query is correctly executed without the occur-check, under any selection rule.

NQUEENS may be considered a somehow unusual program. However similar issues appear with rather typical programs dealing with ground data. Assume, for instance, that data items from a ground data structure are to be copied into two data structures. Program

\[
\text{USE2: } \ p([X|Xs], f(X, XsI), [g(X, \_)|Xs2]) \leftarrow p(Xs, XsI, Xs2). \quad p([], a, []).
\]

provides a concise example. The program is not occur-check free for some 1-ground queries (e.g. for \( p([1], f(Y, Z), [Y|T]) \)). Similarly as for NQUEENS, it can be shown that it is weakly occur-check free for all such queries. For a quick proof see Ex. 17 or 19.

### 3.4 Sufficient conditions for WNSTO

Now we discuss sufficient conditions for safely avoiding the occur-check due to WNSTO. We assume that the programs dealt with are moded.

We say that a selection rule is **compatible with moding** (for a program \( P \) with a query \( Q \)) if (i) the input positions are ground in each selected atom in the SLD-tree for \( P \) with \( Q \) ([AL95] calls this "delay declarations imply the moding"), and (ii) some atom is selected in a query whenever the query contains

---

5USE2 is well-moded under \( p(+, _, _) \), but the approach for well-moded programs does not apply, as the clause head is not output linear. In contrast to NQUEENS, USE2 can be treated as tidy, or nicely moded. The program is tidy under any moding with at most one position +. Hence it is occur-check free for tidy queries (they are a proper subset of 1-ground queries, and include all linear queries).
an atom with its input positions ground. Note that (i) may imply that the selection rule is partial, in the sense that there exist nonempty queries in which no atom is selected. For such a query no resolvent exists, this is called **floundering** (or deadlock).

An atom $A$ is **weakly linear** if any variable $X$ which occurs more than once in $A$ occurs in an input position of $A$. (Speaking informally, grounding the variables in the input positions of $A$ results in a linear atom.)

**Lemma 15** Consider variable disjoint atoms $A$ and $H$, such that the input positions of $A$ are ground, and $H$ is weakly linear. The unification of $A$ and $H$ is WNSTO.

**Proof** Let $A = p(s;t)$, where $s$ is ground, and $H = p(s';t')$. Equation set $s \equiv s'$ is NSTO (by Lemma [1]). Assume that $s \equiv s'$ is unifiable and that $\theta$ is an mgu of $s \equiv s'$. Thus $X \theta$ is ground for each variable $X \in \text{Var}(s')$. Hence $t' \theta$ is linear, and $(t \equiv t') \theta$ is NSTO (by Lemma [1]). Now by Corollary [1] $A \equiv H$ is WNSTO.

It immediately follows:

**Corollary 16** Let $P$ be a program in which each clause head is weakly linear. If the selection rule is compatible with moding then $P$ (with any query) is weakly occur-check free.

**Example 17** The heads of the clauses of NQUEENS are weakly linear under moding $pq(s,+,-,-)$, $pq(-,+,-,-)$. By Corollary [16] the program (with any query) is weakly occur-check free under any selection rule compatible with moding. Consider a query $Q$ which is 1-ground (cf. Section 3.3, p.9). A simple check shows that in any SLD-derivation for NQUEENS and $Q$ all queries are 1-ground. So each selection rule is compatible with moding (for NQUEENS with $Q$). Thus NQUEENS with any 1-ground query is weakly occur-check free for any selection rule. The same reasoning applies to USE2, with $p(+,-,-)$.

Now we provide a syntactic sufficient condition for a program to be weakly occur-check free. It employs a generalized notion of moding, in which some argument positions may be neither + (input) nor − (output), to such positions we assign $\perp$ (neutral). We will call it **3-moding** when it is necessary to distinguish it from a standard moding. We write $p(s;t;u)$ to represent an atom $p(t_1,\ldots,t_n)$ and to state that $s$ (respectively $t$, $u$) is the sequence of terms in its $+$ ($-$, $\perp$) positions. The idea is to distinguish (as + or −) some argument positions which, roughly speaking, deal with ground data. A syntactic sufficient condition will imply for LD-derivations that in each selected atom the input positions are ground.

By a **3-moded** program (or query) we mean one which becomes well-moded [Apt97, Def. 7.8] after removing the $\perp$ argument positions. For a direct definition, let a **defining occurrence** of a variable $V$ in a clause $C = H \leftarrow Q$ be an occurrence of $V$ in an input position of $H$, or in an output position in $Q$. Now $C$ is well-3-moded when each variable $V$ in an output position of $H$ has its defining occurrence in $C$, and each occurrence of $V$ in an input position in $Q$ is preceded by a defining occurrence of $V$ in another literal of $C$ [Dra87]. A query $Q$ is well-3-moded when clause $p \leftarrow Q$ is. An equivalent definition can be obtained by an obvious adaptation of [Apt97, Def. 7.8]. Note that any query with its input positions ground is well-3-moded.

We now use the fact that well-3-moded programs/queries inherit the main properties of well-moded ones.

**Lemma 18** Let $P$ and $Q$ be well-3-moded.

1. All queries in SLD-derivations of $P$ with $Q$ are well-3-moded.
2. For $P$ with $Q$ the Prolog selection rule is compatible with moding.
3. If each clause head in P is weakly linear then P with Q is weakly occur-check free under any selection rule compatible with moding (including the Prolog selection rule). Moreover, if no argument position is moded as output then P with Q is weakly occur-check free under any selection rule.

4. P with Q does not flounder under any selection rule. (I.e. in each query of any SLD-tree for P and Q, there exists an atom with its input positions ground.)

PROOF: 1. An SLD-resolvent of a well-3-moded query and a well-3-moded clause is well-3-moded. The proof is the same as that of the analogical property of well-moded queries and clauses [Apt97, Lemma 7.9]. 2. and 4. From 1. and the fact that the input positions of the first atom of a well-3-moded query are ground. 3. From 2. by Corollary [16]. Additionally, under a 3-moding without −, all input positions in a well-3-moded query are ground. Thus each selection rule is compatible with moding and Corollary [16] applies.

Example 19 Programs NQUEENS and USE2 are well-3-moded under \( pgs(+, ⊥, ⊥, ⊥), pgs(+, ⊥, ⊥, ⊥), \) and \( p(+, ⊥, ⊥); \) so is any 1-ground query. Their clause heads are weakly linear. (The same holds under the modings from Ex. [17]) Thus by Lemma [18.3], the programs are weakly occur-check free for 1-ground queries, under any selection rule. So we obtained by syntactic means the results of Ex. [17].

Example 20 Apt and Pellegrini [AP94] use program DERIVATIVE [SS94, Program 3.30] as an example for an approach combining those for well-moded and nicely moded programs. Here are representative clauses of the program (infix operators ↑, * are used).

\[
\text{DERIVATIVE:} \quad \begin{align*}
d(X, X, s(0)). \\
d(X↑s(N), X, s(N)↑X↑N). \\
d(F↑G, X, F↑DG↑DF↑G) & \leftarrow d(F, X, DF), d(G, X, DG).
\end{align*}
\]

A typical query is \( d(e, x, t), \) where \( e, x \) are ground (\( e \) represents an expression, and \( x \) a variable), \( t \) is often a variable. Here moding \( d(+, ⊥, ⊥) \) will be sufficient. Consider a query \( Q = d(e_1, x_1, t_1), \ldots, d(e_n, x_n, t_n) \) where \( e_1, \ldots, e_n \) are ground. DERIVATIVE and \( Q \) are well-3-moded moded under \( d(+, ⊥, ⊥) \). Also, the clause heads are weakly linear. By Lemma [18.3], the program with \( Q \) is weakly occur-check free under any selection rule.

Alternatively, let us find a mode \( m_d \) under which the program is tidy. The moding of the second argument, \( m_d(2) \), must be +, otherwise the clause body is not output linear. As the clause heads have to be input linear, \( m_d(1) = m_d(3) = − \). Under \( d(−, +, −) \) the program turns out to be tidy. Hence, by Corollary [4] under any selection rule the program is occur-check free for tidy queries, including any linear queries. See Ex. [27] for a yet another class of queries under which the program is weakly occur-check free.

[AP94] applied a combination of methods of well-moding and nice moding to show that DERIVATIVE is occur-check free for an atomic \( Q (n = 1) \) with ground \( e_1, x_1 \) and linear \( t_1 \), under LD-resolution. Surprisingly, a more general result can be obtained by a simpler approach from that work. Under \( d(−, +, −) \) DERIVATIVE is nicely-moded and its clause heads are input linear. Thus it is occur-check free under LD-resolution for any nicely moded queries, this includes any linear queries. Still, this result is subsumed by each of our two conclusions above (and by the result of Ex. [27]).

In this section we dealt with clause heads whose certain instances are linear. Appendix [C] employs clauses whose certain instances are tidy, to construct another sufficient condition for weak occur-check freeness.
4 Comments

Let us first discuss briefly the limits of applicability of the presented results. The approaches discussed here are based on conditions imposed on clauses and queries. The conditions treat any predicate argument as a single entity, and refer to groundness or to placement of variables within certain argument positions. This may be not sufficient when the occur-check depends on other features of the terms in argument positions. For instance, in the SAT-solver of Howe and King [HK12] an argument is a non-linear list of lists of pairs, and occur-check freeness depends on the first element of each pair being ground [Dra18]. In such cases our methods fail, and some analysis of the queries in SLD-trees is needed instead. One may expect that introducing a suitable type system could be useful.

Introduction of WNSTO has two consequences. Some cases where unification is not NSTO can actually be safely executed without the occur check. Also, reasoning based on WNSTO is sometimes simpler. For instance, showing that program NQUEENS is occur-check free was substantially more complicated than showing it to be weakly occur-check free for a wider class of queries.

Most of the employed sufficient conditions are based on the notion of modes. Examples show that modes (except for well-moded programs) do not need to correspond to any intuitive understanding of data flow. Instead, they deal with how variables are placed in argument positions. An output argument may well be used for input data. Neglecting this fact may be the reason why in some examples of [AP94] unnecessarily complicated methods were applied, or more general results could have been obtained. (For examples and explanations see the comments on FLATTEN and NORMALIZE in Section 2.2 and on DERIVATIVE in Ex. 20.)

Conclusions The main contribution of this paper is weakening the notion of NSTO (not subject to occur-check) used in the previous work on avoiding the occur-check. Additionally, we present a sufficient condition based on NSTO, generalizing the approach based on nicely moded programs.

We generalize NSTO to WNSTO (weakly NSTO). This leads to a generalization of the notion of occur-check free programs/queries (based on NSTO) to weakly occur-check free ones (based on WNSTO). We proved that unification without the occur-check is sound for any input which is WNSTO. We presented a few sufficient conditions for WNSTO, and for a program/query being weakly occur-check free. Some conditions are syntactic, like Lemma 18; some refer to semantic notions, like Corollary 16 which explicitly refers to details of SLD-derivations. Examples show that the proposed approach makes it possible to omit the occur-check in cases, to which the approaches based on NSTO are inapplicable. In some other cases, it leads to simpler proofs.

A Appendix. Proof of Lemma 3

The proof is preceded by some auxiliary definitions and results.

Definition 21 Let $E$ be a set of variables. A substitution $\theta$ is linear for $E$ if for any two distinct variables $X,Y \in E$ the pair $X\theta,Y\theta$ is linear. If $E = \{X\}$ is a singleton then we require that $X\theta$ is linear.

$\theta$ is linear for an expression $t$ if $\theta$ is linear for $\text{Var}(t)$.

Obviously, if $\theta$ is linear for a set $E$ then it is linear for any $E' \subseteq E$. A $\theta$ linear for $\text{Dom}(\theta)$ is linear in the sense of [AP94, Def. A.3] (this means that if $\theta = \{X_1/t_1, \ldots, X_n/t_n\}$ then $t_1, \ldots, t_n$ is linear).

Lemma 22 If $\theta$ is linear for a linear expression $t$ then $t\theta$ is linear.
Lemma 23 Let \( \theta \) be a substitution and \( X, V, V' \) variables. Assume that \( X \in \text{Var}(V\theta) \) and \( X \in \text{Var}(V'\theta) \). Then \( X = V = V' \), or \( X, V, V' \in \text{Var}(\theta) \) and moreover \( X \in \text{Ran}(\theta) \).

Proof Assume \( X \notin \text{Ran}(\theta) \). Then \( X \in \text{Var}(V) \), thus \( X = V \). In the same way we obtain \( X = V' \).

Assume \( V \notin \text{Var}(\theta) \). Hence \( V\theta = V = X \), and \( V \in \text{Var}(V'\theta) \) implies \( V = V' \). In the same way, \( V' \notin \text{Var}(\theta) \) implies \( X = V = V' \).

Lemma 24 Consider two variable disjoint expressions \( s, t \) where \( t \) is linear. Let \( \mathcal{S} \) be a set of variables such that \( \mathcal{S} \cap \text{Var}(t) = \emptyset \). If \( s, t \) are unifiable then there exists a relevant and idempotent mgu \( \theta \) of \( s, t \) such that

- \( \theta|s \) is linear for \( \mathcal{S} \), and
- \( \text{Ran}(\theta|s) \subseteq \text{Var}(t) \).

Proof Without loss of generality, assume that \( s, t \) are terms. We refer to the nondeterministic Robinson algorithm (NRA) as described in [Apt97] p. 28. We will consider a run of NRA on \( s \) and \( t \).

We first simplify the notion of access path from [Apt97] (p. 27). Let access path for a term \( s \) be a sequence of numbers defined recursively as follows. The empty sequence \( () \) points at the main symbol of \( s \) (the root of the tree \( T_s \) associated with \( s \)). If \( \pi \) is an access path pointing at an occurrence of a term \( u = f(u_1, \ldots, u_m) \) in \( s \) (the root of the subtree \( T \) of \( T_s \), associated with the occurrence of \( u \)) then \( \pi, i \) is the access path pointing at the \( i \)-th child of the root of \( T \), for \( i = 1, \ldots, m \). Now consider a disagreement pair of some terms \( s', t' \). The two elements of the pair have the same access path in \( s' \) and in \( t' \).

The mgu of \( s, t \) produced by NRA is \( \theta = \gamma_1 \cdots \gamma_k \), where \( \gamma_1, \ldots, \gamma_k \) are the substitutions determined by the disagreement pairs considered in the consecutive steps of the NRA [Apt97] p. 28. Each \( \gamma_i \) is of the form \( \gamma_i = \{X_i/u_i\} \), where \( \{X_i/u_i\} \) is the corresponding disagreement pair of the pair of terms \( s\beta_i, t\beta_i \), where \( \beta_i = \gamma_i \cdots \gamma_{i-1} \). All \( X_1, \ldots, X_k \) are distinct, each \( X_i \) does not occur in \( u_i \).

Let us say that access paths \( \pi, \pi' \) are independent if none of them is a prefix of the other. Let \( \pi_i \) be the access path of the disagreement pair \( \{X_i, u_i\} \) considered in step \( i \). Note that \( \pi_1, \ldots, \pi_k \) are distinct and pairwise independent. Let \( I \) be the set of the indices of those disagreement pairs for which a variable from the first term is replaced. More precisely \( I = \{i \mid X_i \in \text{Var}(s\beta_i)\} \).

Now we show by induction on \( i \) that, for \( 0 \leq i \leq k \),

- for any access path \( \pi \) independent from \( \pi_1, \ldots, \pi_i \), if \( \pi \) points at a subterm \( t' \) in \( t\beta_{i+1} \) then \( \pi \) points at \( t' \) in \( t \) (and \( t' = t\beta_{i+1} \)). Moreover,
  - \( \text{Var}(t') \cap \text{Var}(\gamma_1, \ldots, \gamma_i) = \emptyset \),
  - \( \text{Ran}(\beta_{i+1}|s) \subseteq \text{Var}(s) \), and
  - \( \beta_{i+1}|s \) is linear for \( \mathcal{S} \).

For \( i = 0 \) the claim is obvious. Assume that the claim holds for \( i - 1 \). As \( \pi_i \) is independent from \( \pi_1, \ldots, \pi_{i-1} \), the term \( u = u\beta_i \) pointed at by \( \pi_i \) in \( t \) is pointed at by \( \pi_i \) in \( t\beta_i \). Consider a path \( \pi \) independent from \( \pi_1, \ldots, \pi_i \), and the term \( t' = t\beta_i \) pointed at by \( \pi \) in \( t \) and \( t\beta_i \).

Note first that \( \text{Var}(t') \cap \text{Var}(u) = \emptyset \), as \( t', u \) are subterms of the linear \( t \), and their access paths are independent. Also, \( \text{Var}(s\beta_i) \cap \text{Var}(u, t') = \emptyset \), as \( \text{Var}(s\beta_i) \subseteq \text{Var}(s) \cap \text{Var}(\gamma_1, \ldots, \gamma_{i-1}) \), and each subterm of \( t \) is variable disjoint with \( s \), and by the inductive assumption \( \text{Var}(u, t') \cap \text{Var}(\gamma_1, \ldots, \gamma_{i-1}) = \emptyset \). Now one
element of \( \{X_i, u_i\} \) is \( u \) and the other one is a subterm of \( sB_i \). Each of them is variable disjoint with \( t' \).
Thus \( \text{Var}(\gamma) \cap \text{Var}(t') = \emptyset \), as \( \gamma = \{X_i/u_i\} \). Hence \( \text{Var}(t') \cap \text{Var}(\gamma, \ldots, \gamma) = \emptyset \).

There are two cases. (a) \( u \not\in X_i \) (i.e. \( i \in I \) and \( u = u_i \)). Then \( X_i \) is a subterm of \( sB_i \), the latter is variable disjoint from \( t' \), as shown above. Hence \( X_i \not\in \text{Var}(t') \), and thus \( t' = t'\gamma \). (b) \( u = X_i \) (i.e. \( i \not\in I \)). Then \( \text{Var}(t') \cap \{X_i\} = \emptyset \) as shown above, and thus \( t' = t'\beta_i \). In both cases we obtain \( t' = t'\beta_i \).

Let us look at \( \beta_{i+1}|s \). In case (b), as \( X_i = u \) is variable disjoint with \( sB_i \), we have \( sB_i \gamma = sB_i \), hence \( \text{Ran}(\beta_{i+1}|s) = \text{Ran}(\beta_i|s) \subseteq \text{Var}(t) \) (the inclusion is a part of the inductive assumption). In case (a), \( \text{Var}(\gamma) = \text{Var}(u) \subseteq \text{Var}(t) \). Hence \( \text{Ran}(\beta_{i+1}|s) \subseteq \text{Ran}(\beta_i|s) \cup \text{Ran}(\gamma) \subseteq \text{Var}(t) \). We showed that \( \text{Ran}(\beta_{i+1}|s) \subseteq \text{Var}(t) \).

It remains to show that \( \beta_{i+1}|s \) is linear for \( \mathcal{S} \). As \( \text{Dom}(\beta_i) \subseteq \text{Var}(s, t) \) and \( \text{Var}(s) \cap \text{Var}(t) = \emptyset \), we have \( \beta_i = (\beta_i|s) \cup (\beta_i|t) \). Similarly \( \beta_{i+1} = (\beta_{i+1}|s) \cup (\beta_{i+1}|t) \). Consider a variable \( Z \in \mathcal{S} \). We have \( Z \not\in \text{Var}(t) \) and thus \( Z(\beta_i|s) = Z\beta_i \) and \( Z(\beta_{i+1}|s) = Z\beta_{i+1} \). Note that \( Z\beta_i \) is linear, by the inductive assumption. Note also that \( \text{Var}(Z\beta_i) \cap \text{Var}(u) = \emptyset \) (due to \( \text{Var}(Z\beta_i) \subseteq \{Z\} \cup \text{Var}(\beta_i) \subseteq \{Z\} \cup \text{Var}(\gamma, \ldots, \gamma_{i-1}) \): now \( \{Z\} \cap \text{Var}(u) = \emptyset \) as \( Z \not\in \text{Var}(t) \), and \( \text{Var}(\gamma, \ldots, \gamma_{i-1}) \cap \text{Var}(u) = \emptyset \) as shown above).

In case (a), \( Z\beta_i \gamma = Z\beta_i \) (which is linear, by the inductive assumption) or \( Z\beta_i \gamma \) is obtained from \( Z\beta_i \) by replacing a single occurrence of \( X_i \) by \( u \). Such \( Z\beta_i \gamma \) is linear, as \( u \) is linear and \( \text{Var}(Z\beta_i) \cap \text{Var}(u) = \emptyset \). In case (b), \( X_i = u \in \text{Var}(t) \). Thus \( Z\beta_i \gamma = Z\beta_i \) (as \( \text{Var}(Z\beta_i) \cap \text{Var}(u) = \emptyset \)). So \( Z\beta_i \gamma \) is linear in both cases (a) and (b).

To show that \( \beta_{i+1}|s \) is linear for \( \mathcal{S} \), it remains to show, for any distinct variables \( X, Y \in \mathcal{S} \), that \( (X, Y)(\beta_{i+1}|s) = (X, Y)\beta_{i+1} \gamma \) is linear. Note that \( Z\beta_{i+1} \gamma = Z\beta_i \) if \( X_i \not\in \text{Var}(Z\beta_i) \). Let \( X, Y \in \mathcal{S} \). As by the inductive assumption \( (X, Y)\beta_i \) is linear, \( X_i \) occurs in at most one of the terms \( X\beta_i \) and \( Y\beta_i \). Assume \( X_i \) occurs in one of them, say \( X_i \in \text{Var}(X\beta_i) \). Case (b) is excluded (as shown above), so \( \gamma = \{X_i/u\} \). Then \( \text{Var}(X\beta_i \gamma) \subseteq \text{Var}(X\beta_i) \cup \text{Var}(u) \). As shown previously, \( \text{Var}(Y\beta_i) \cap \text{Var}(u) = \emptyset \). As also \( \text{Var}(Y\beta_i) \cap \text{Var}(X\beta_i) = \emptyset \), we obtain \( \text{Var}(Y\beta_i) \cap \text{Var}(X\beta_i \gamma) = \emptyset \). Hence \( X\beta_{i+1} \gamma, Y\beta_{i+1} \gamma \) is linear, as \( Y\beta_{i+1} \gamma = Y\beta_i \), and both \( Y\beta_i \) and \( X\beta_{i+1} \gamma \) are linear. The remaining case is \( X_i \) not occurring in \( (X, Y)\beta_i \). Then \( (X, Y)\beta_{i+1} \gamma = (X, Y)\beta_i \), which is linear.

This completes the inductive proof. For \( i = k \) the proved claim implies the Lemma.
mgp $\rho$ of $t_1$ and $t_\sigma$ can be chosen so that

$$\rho \parallel \sigma \text{ is linear for } Var(t_\sigma, Q_B \sigma) \cup S_{uQ} \text{ and } Ran(\rho \parallel \sigma) \subseteq Var(t_1).$$

Thus

$$Q'_0 = (Q_B, A_2, \ldots, A_n) \sigma(\rho \parallel \sigma) \quad \text{is output linear}$$

(as $(Q_B, Q) \sigma$ is). Note now that $\rho = (\rho \parallel \sigma) \cup (\rho | t_1)$. Hence for any $u \in \{Q_B \sigma, t_2 \sigma, \ldots, t_n \sigma\}$ we have $u(\rho | \sigma) = u\rho$ (as $u$ and $t_1$ are variable disjoint). Thus

$$Q' = (Q_B, A_2, \ldots, A_n) \sigma \rho \quad \text{is output linear}$$

(as its output positions are those of $Q'_0$).

We proved that the SLD-resolvent $Q'$ of $Q$ and $C$ is output linear. It remains to show that $\rightarrow_{Q'}$ is acyclic. We consider all atom pairs $A', A''$ such that $A' \rightarrow_{Q'} A''$, and relate them to relations $\rightarrow_Q$ and $\rightarrow_{Q_B}$.

1. Assume that $B_i \theta \rightarrow_{Q'} B_j \theta$ (for some $i, j \in \{1, \ldots, m\}$). So there is $X \in VarOut(B_i \theta) \cap VarIn(B_j \theta)$. Obviously $B_i \sigma, B_j \sigma$ are non-ground (as they have non-ground instances). There exist variables $V, V'$ such that $X \in VarOut(B_i \sigma), V' \in VarIn(B_j \sigma)$, and $X \in Var(V \rho), X \in Var(V' \rho)$. As $\rho \parallel \sigma = \rho \parallel C \sigma$ is linear for $Var(Q_B \sigma)$, and $V \rho, V' \rho$ is not linear, we obtain that $V = V'$. So $B_i \sigma \rightarrow_{Q_B} B_j \sigma$.

Let $B_i = q(s', t')$. $t' \sigma = t'$ (as $Var(\sigma) \subseteq Var(s, s_1)$ and no variable from $s, s_1$ occurs in $t'$). So $V \in Var(t')$, hence $V \notin Var(\sigma)$ and $V \in Var(B_j)$). Hence $B_i \rightarrow_{Q_B} B_j$.

2. Assume that $A_i \theta \rightarrow_{Q'} A_j \theta$ (for some $i, j \in \{2, \ldots, n\}$). So there is $X \in VarOut(A_i \theta) \cap VarIn(A_j \theta)$. As above, there exist $V, V'$ such that $V \in VarOut(A_i \sigma), V' \in VarIn(A_j \sigma)$, and $X \in Var(V \rho), X \in Var(V' \rho)$.

(But that $X, V, V'$ may be not distinct.) As $Q'$ is output linear, $X$ occurs exactly once in the output positions of $(A_i, \sigma \rho)$, and $V$ is unique.

There exist $W, W' \in Var(Q)$ such that $V \in Var(W \sigma), V' \in Var(W' \sigma)$. $W \in VarOut(A_i)$ and $W' \in VarIn(A_j)$. Note that $W \notin Var(t_1)$ (as $Q$ is output linear). Employing $W$ and $W'$ we are going to show that $A_i \rightarrow_{Q} A_j$.

If $W = W'$ the claim is obvious (as $A_i \rightarrow_{Q} A_j$). So assume $W \neq W'$.

Thus $V \neq V'$ (as $\sigma(Q = \sigma | s_1$ linear for $Var(Q)$). From $X \in Var(V \rho) \cap Var(V' \rho)$, by Lemma 23 we obtain $V, V', X \in Var(\rho)$ and moreover $X \in Ran(\rho)$.

We have two possibilities (a) $V \neq W$, hence $W \in Dom(\sigma)$; otherwise (b) $V = W$. In (b) $W \in Var(\rho) \subseteq Var(t_1, t_\sigma)$; hence $W \in Var(t_\sigma)$ (as $W \notin Var(t_1)$); thus $W \in Var(\sigma)$ (as $W \notin Var(H)$). So in both cases $W \in Var(\sigma) \subseteq Var(s_1, s)$, hence $W \in Var(s_1) = VarIn(A_1)$ (as $W \notin Var(H)$). Thus $A_i \rightarrow_{Q} A_1$.

Note that $V, V'$ cannot both occur in $\sigma$ (as $\rho | \sigma$ is linear for $Var(\sigma)$). As $(Q_B, Q) \sigma$ is output linear, $V$ does not occur in $t_1 \sigma = t_1$. As $V, V' \in Var(\rho) \subseteq Var(t_1, t_\sigma)$, it follows that $V'$ occurs in $t_1$. Thus $V' = V' \sigma$ and $W' = V'$. Hence $W' \in Var(t_1) \cap VarIn(A_1)$, so $A_i \rightarrow_{Q} A_1$.

We showed that $A_i \theta \rightarrow_{Q'} A_j \theta$ implies $A_i \rightarrow_{Q} A_j$ where $l = 1$ or $l = 2$.

3. Assume that $A_i \theta \rightarrow_{Q'} B_j \theta$ (for some $i \in \{2, \ldots, n\}, j \in \{1, \ldots, m\}$). So there is $X \in VarOut(A_i \theta) \cap VarIn(B_j \theta)$. As above, there exist $V, V'$ such that $V \in VarOut(A_i \sigma), V' \in VarIn(B_j \sigma)$, and $X \in Var(V \rho), X \in Var(V' \rho)$. Then there exist $W, W'$ such that $W \in VarOut(A_i), W' \in VarIn(B_j), V \in Var(W \sigma)$ and $V' \in Var(W' \sigma)$.

Now we show that $W \in Var(s_1)$, by considering two possibilities. Assume $V = V'$. As $W \neq W'$, by Lemma 23 we obtain $V, W, W' \in Var(\sigma) \subseteq Var(s_1, s)$. Thus $W \in Var(s_1)$. Assume now $V \neq V'$. Exactly as in case 2 (by applying Lemma 23 and then considering possibilities (a) $V \neq W$ and (b) $V = W$) we obtain $W \in Var(s_1)$. As $s_1$ are the input positions of $A_1$, we showed that $A_i \theta \rightarrow_{Q'} B_j \theta$ implies $A_i \rightarrow_{Q} A_1$.  

4. Assume that $B_j \theta \rightarrow_{\mathcal{O}} A_i \theta$ (for some $i \in \{2, \ldots, n\}$, $j \in \{1, \ldots, m\}$). So there is an $X \in \text{VarOut}(B_j \theta) \cap \text{VarIn}(A_i \theta)$. Note first that $B_j \sigma$ and $B_j$ have the same terms in their output positions, as $\text{VarOut}(B_j) \cap \text{Var}(s, s) = \emptyset$. So there exist $W, V'$ such that $X \in \text{Var}(W \rho)$, $X \in \text{Var}(V' \rho)$, and $W \in \text{VarOut}(B_j) = \text{VarOut}(B_j)$ (and $W = W \sigma$, $V' \in \text{VarIn}(A_i \sigma)$). Also, there exists $W'$ such that $W' \in \text{VarIn}(A_i)$ and $V' \in \text{Var}(W' \sigma)$.

As $W \in \text{VarOut}(B_j)$ and clause $H \leftarrow Q_B$ is tidy, $W \not\in \text{Var}(s, s)$ and thus $W \not\in \text{Var}(\sigma)$. Hence $W \not\in \text{Var}(Q)$ implies $W \not\in \text{Var}(A_i \sigma)$. As $V' \in \text{VarIn}(A_i \sigma)$, we obtain $V' \neq W$. Thus, by Lemma 23, $X, V', W \in \text{Var}(\rho)$. Hence $W \in \text{Var}(t, t \sigma)$ and thus $W \in \text{Var}(t \sigma)$ (as $W \not\in \text{Var}(Q)$).

From $X \in \text{Var}(W \rho)$ and $W \in \text{Var}(t \sigma)$ we obtain $X \not\in \text{Var}(U \rho)$ for any variable $U \neq W$ occurring in $t \sigma$ (as $\rho \not\in \text{Var}(t \sigma)$). As $X \in \text{Var}(V' \rho)$, $V'$ does not occur in $t \sigma$. Thus $V' \in \text{Var}(t_1)$. Hence $V' \not\in \text{Var}(\sigma)$ and $V' \in \text{Var}(W' \sigma)$ implies $V' = W'$.

Thus $W'$ occurs in an output position of $A_i$ and an input position of $A_j$. We showed that $B_j \theta \rightarrow_{\mathcal{O}} A_i \theta$ implies $A_1 \rightarrow_{\mathcal{O}} A_j$.

Now assume that $\rightarrow_{\mathcal{O}}$ has a cycle $\mathcal{C}$. Suppose $\mathcal{C}$ contains only atoms from $Q_B \theta$, say $\mathcal{C}$ is $B_1 \gamma_1 \cdots B_k \gamma_k \theta$ (for some $k, i_1, \ldots, i_k \in \{1, \ldots, m\}$). Then $B_{i_1}, \ldots, B_{i_k}$ is a cycle in $Q_B$. Contradiction, as $H \leftarrow Q_B$ is tidy. In the same way it follows that $\mathcal{C}$ cannot contain only atoms from $Q'$, as $Q$ is tidy. So $\mathcal{C}$ contains two pairs of atoms $A_i \theta \rightarrow_{\mathcal{O}} B_j \theta$ and $B_j \theta \rightarrow_{\mathcal{O}} A_i \theta$ (for some $i, j \in \{1, \ldots, m\}$). We also have $A_i \theta \rightarrow_{\mathcal{O}} A_j \theta$. Hence $A_1 \rightarrow_{\mathcal{O}} A_2 \rightarrow_{\mathcal{O}} \cdots \rightarrow_{\mathcal{O}} A_i \theta$. Hence $A_1 \rightarrow_{\mathcal{O}} A_2 \rightarrow_{\mathcal{O}} \cdots \rightarrow_{\mathcal{O}} A_i \theta$. Contradiction; $\rightarrow_{\mathcal{O}}$ is acyclic. Hence $Q'$ (previously shown to be output linear) is tidy.

Any resolvent $Q''$ of $Q$ (with selected $A_1$) and a variant of $H \leftarrow Q_B$ is a variant of $Q'$, hence $Q''$ is tidy.

### B Appendix. Proof of Lemma 10

The proof employs a technical lemma.

**Lemma 25** Consider a run $R$ of MMA producing an mgu $\theta$. Let $X_1 \doteq t_1, \ldots, X_k \doteq t_k$ (in this order) be the equations selected in action (5) in $R$, and $\gamma = \{X_i/t_i\}$ for $i = 1, \ldots, k$. Then $\theta = \gamma_1 \cdots \gamma_k$. Moreover, the last equation set of $R$ is $\{X_i = t_i \gamma_i \cdots \gamma_k \mid 0 < i \leq k\}$.

**Proof** Action (5) means applying $\gamma_i$ to all the equations except for $X_i \doteq t_i$. Moreover, (a current instance of) $X_i \doteq t_i$ is not selected anymore in $R$. So $\theta$ contains a pair $X_i/t_i \gamma_i \cdots \gamma_k$. Let $\psi_j = \{X_i/t_i \gamma_i \cdots \gamma_j \mid 0 < i \leq j\}$ and $\varphi_j = \gamma_i \cdots \gamma_j$, for $j = 0, \ldots, k$. Now $\psi_j = \varphi_j$, by induction on $j$ (as $\psi_j/t_i \gamma_i \cdots \gamma_j \mid 0 < i \leq j$ for $\gamma_i \cdots \gamma_j \mid 0 < i \leq j$). Thus $\theta = \varphi_k$.

**Proof of (Lemma 10)** Assume that $E_1$ is not unifiable. Then from a run $R$ of MMA on $E_1$ one can construct in an obvious way a run $R'$ of MMA on $E_1 \cup E_2$, performing the same actions and selecting the same equations. Thus action (6) is not performed in $R'$.

Now assume that $\theta_1$ is an mgu of $E_1$. Consider a run $R_1$ of MMA on $E_1$, and a run $R_2$ of MMA on $E_2 \theta_1$. Without loss of generality we may assume that $\theta_1$ is the result of $R_1$. (Otherwise, $R_1$ produces $\theta$ such that $E_2 \theta_1$ is a variant of $E_2 \theta$.)

Let step (5) be applied in $R_1$ to equations $X_1 \doteq t_1, \ldots, X_k \doteq t_k$ (in this order), and in $R_2$ to $X_{k+1} \doteq t_{k+1}, \ldots, X_m \doteq t_m$ (in this order). Let $\gamma_i = \{X_i/t_i\}$, for $i = 1, \ldots, m$. Let $F$ be the last equation set in $R_1$; by Lemma 25, $F = \{X_1 \doteq t_1 \gamma_2, \ldots, \gamma_k\}$. We construct a run $R$ of MMA on $E_1 \cup E_2$, for each equation set from $R_1$ or $R_2$ we construct a corresponding equation set from $R$. 

Consider an equation set $E$ in $R_1$. Let $X_1 \leftarrow t_1, \ldots, X_i \leftarrow t_i$ be the equations on which action (5) has been performed in $R_1$ until obtaining $E$ ($i \in \{0, \ldots, k\}$). The equation set corresponding to $E$ is $E' = E \cup E_2 \gamma_1 \cdots \gamma_i$. In particular (by Lemma 25), $F \cup E_2 \theta_1$ corresponds to the last equation $F$ of $R_1$.

For $i \in \{k, \ldots, m\}$ let us define $F_i = \{X_1 \leftarrow t_1 \gamma_1 \cdots \gamma_i \mid 0 < i \leq k\}$. Note that $F_i = F$. Consider an equation set $E$ in $R_2$. Let $X_{k+1} \leftarrow t_{k+1}, \ldots, X_i \leftarrow t_i$ be the equations on which action (5) has been performed in $R_2$ until obtaining $E$ ($i \in \{k, \ldots, m\}$). The equation set corresponding to $E$ is $E' = F_i \cup E$.

Consider now the sequence consisting of the equation sets corresponding to those of $R_1$ and then of the equation sets corresponding to those of $R_2$ (without the first one, to avoid a repetition of $F \cup E_2 \theta_1$). The sequence is a run of MMA on $E_1 \cup E_2$. As the run does not involve action (6), $E_1 \cup E_2$ is WNSTO. □

C  Appendix. Another syntactic sufficient condition

Here we present a sufficient condition for avoiding the occur-check, related to WNSTO and based on the syntactic conditions for tidy programs.

Consider a 3-moding $M$ and an additional moding $M'$, for the latter we use symbols $+', '-'$. Consider transforming each clause $C$ of a program $P$, by grounding the variables that occur in the $+$ positions in the head. Let $P'$ be the resulting program. Let us say that $P$ is weakly tidy (under $M, M'$) if $P'$ is tidy under $M'$.

For an example, consider a program $P$ containing a clause $C$ with body $B = q(X, Y), q(Y, Z), q(Z, X)$. Assume also that $P$ contains a clause head $H = q(t, u)$ with $t, u$ containing a common variable. For $P$ to be tidy, the argument positions of $q$ cannot be both input (due to $H$), and cannot be both output (due to $B$). However, if they are $(+, -)$, or $(-, +)$ then $-B$ is cyclic. Thus $P$ is not tidy (and not nicely moded) under any moding. Assume now that $C$ is $p(X) \leftarrow B$. Under $p(+)$, and $q(+', '-'$) the clause is weakly tidy. (A corresponding clause of $P'$ is $p(s) \leftarrow q(s, Y), q(Y, Z), q(Z, s)$, for a ground term $s$; note that $q(+', '-'$ may be replaced by $q(-', '+'$.) By the lemma below, if $p(s)$ is selected in a tidy query $Q$ then the resolvent of $Q$ and $C$ is tidy.

Lemma 26 Let $P$ be a weakly tidy program under $M, M'$, and $Q$ a query tidy under $M'$. Under any selection rule compatible with $M$

each query in any SLD-derivation for $P$ with $Q$ is tidy under $M'$, and $P$ with $Q$ is weakly occur-check free.

Proof Let $A$ be the selected atom of a tidy (under $M'$) query $Q$, and $H$ be the head of a standardized apart clause $C$ of $P$. Let $A = p(s; t; u)$ and $H = p(s'; t'; u')$ (under $M$). Unifying $A$ with $H$ can be divided in two steps: \[\text{[Apt97] Lemma 2.24}.\]

1. Unifying $s$ with $s'$. As $s$ is ground, $s \equiv s'$ is NSTO.
2. Unifying $(t, u \equiv t', u')\theta$ provided that $s \equiv s'$ is unifiable with an mgu $\theta$ . This is the same as unifying $A\theta = H\theta$ (as $s\theta = s'\theta$ and is ground). Note that $Q\theta = Q$ (thus $A\theta = A$), and that $C\theta$ is tidy under $M'$. So $A\theta$ is an atom from a tidy query, and $H\theta$ is the head of a standardized apart tidy clause $C\theta$. By Corollary 4, $A\theta = H\theta$ is NSTO.

Now by Corollary 11 $A \vdash H$ is WNSTO. If $A \vdash H$ is unifiable then, by Lemma 3 the resolvent $Q'$ of $Q\theta$ and $C\theta$ is tidy. $Q'$ is also the resolvent of $Q$ and $C$.

We showed, for a tidy query $Q$ and a standardized apart clause $C$ of $P$, that unification of the selected atom of $Q$ with the head of $C$ is WNSTO, and that the resolvent (if it exists) of $Q$ with $C$ is tidy. The Lemma follows by simple induction. □
Consider $P, Q$ satisfying the conditions of the Lemma. If $P$ and $Q$ are well-3-moded under $M$ then $P$ with $Q$ is weakly occur-check free under Prolog selection rule (and under any selection rule compatible with $M$, under such rule it does not flounder).

**Example 27**  Program DERIVATIVE is weakly occur-check free for some queries not considered in Ex.20. Consider modings $M = d(\bot,+,\bot)$ and $M' = d(+',\bullet,-')$, where $\bullet$ stands for $+'$ of $-'. DERIVATIVE$ is weakly tidy under $M, M'$ (as DERIVATIVE with $X$ replaced by a constant is tidy under $M'$). Assume an initial query $Q = d(e_1,x_1,t_1),\ldots,d(e_n,x_n,t_n)$, where terms $x_1,\ldots,x_n$ are ground. Then each selection rule is compatible with $M$. By Lemma 26 if $Q$ is tidy under $M'$ then DERIVATIVE with $Q$ is weakly occur-check free, under any selection rule.

An example of such query is any $Q = d(e,a,t)$, where $t$ is linear and variable disjoint with $e$ (and $a$ is ground). Note that when $e$ is not linear then such query is not dealt with by the sufficient conditions presented in Ex.20.
