I. INTRODUCTION

Topological quantum states have been an object of great interest to physicists over the last few decades due to their curious properties [1, 3]. Starting with the discovery of the quantized conductivity in the quantum Hall effect [4], the field has developed a series of exciting discoveries in modern topics like topological insulators [5, 6], Weyl semimetals [7, 8], and topological superconductors [9, 12]. At the same time, topological phenomena offer promising applications. For example, non-interacting topological models, represented by the band theory, give rise to the field of spintronics [13], while certain interacting models are predicted to lead to ground-breaking new applications such as topological quantum computing [14].

A great success of modern condensed matter theory is the discovery of that topological phases of matters are generally subject to topological invariants related to the global symmetries [15]. These invariants were originally connected to the phases of quantum systems. Still, recent studies have shown that a number of topological phenomena initially observed in non-interacting quantum systems are reproducible in purely classical systems [16, 23]. In this work, we put forward a new concept of topology-stabilized quantum entanglement inspired by such classical topological materials and introduce a bottom-up method to engineer topological quantum devices. Specifically, we propose a method to generate long-range entangled states of topological modes in a one-dimensional (1D) system and provide a detailed proposal based on coupled superconducting resonators and qubits. Our proposal sets a novel approach for generating long-lived quantum modes with robustness towards disorder in the circuit parameters via a bottom-up experimental approach relying on easy-to-engineer building blocks.

In Sec. [IV] we statistically analyze the stability of such topological entanglement in the presence of parameter fluctuations. In Sec. [V] we discuss practical methods to address topological entanglements in disordered systems. Finally, in Sec. [VI] we give a conclusion of our study and discuss the outlook.

II. SU-SCHRIEFFER-HEEGER MODEL

The Su-Schrieffer-Heeger (SSH) model [24] is a prominent simple non-interacting model exhibiting topological properties. It was proposed to describe spinless fermions hopping on a one-dimensional lattice with staggered hopping amplitudes [24]. This model leads to topological edge modes supported on the ends of a lattice in the topologically non-trivial phase, see Fig. 1(c). While originally proposed for fermions, the model can readily be implemented as an array of superconducting resonators [25], see Fig. 1(b).

The SSH Hamiltonian [24] is given by

$$H = \sum_{n=1}^{N} (v_n c_{n,A}^\dagger c_{n,B} + w_n c_{n,B}^\dagger c_{n+1,A} + \text{h.c.}),$$

where $c_{n,a}^\dagger$ ($c_{n,a}$) is the creation (annihilation) of a particle on lattice site ($n, a$) with lattice index $n \in [1, N]$ and sublattice index $a \in A, B$. The intra-cell to inter-cell hopping ratio, $v/w$, controls the topological phase transition. The model is in the topologically non-trivial phase at $v/w < 1$ where two mid-gap states exist. Such states are exponentially localized at the edge lattices, as shown in Fig. 1(c). The two edge modes are robust towards arbitrary disorder as long as the disorder respects the chiral symmetry of the Hamiltonian. The energy gap closes at $v/w = 1$, which indicates the topological phase transition. When $v/w > 1$, the model is in the trivial phase where two mid-gap edge states merge into the bulk band, and the edge localization is no longer valid. In the context of superconducting circuits, resonator transmission.
and reflection measurements can readily confirm the appearance of the mid-gap modes in the topological phase of the SSH model. We provide a detailed discussion of the SSH model and its spectrum in Appendix A.

III. ENTANGLING THE TOPOLOGICAL MODES

In the context of quantum entanglement, we propose a scheme to entangle two spatially separated topological SSH edge modes and investigate the robustness of such entanglement against disorders. This task can be accomplished by engineering a system consisting of a single qubit and two 1D SSH arrays, see Fig. 2(a). In Fig. 2(b) we show how this architecture can be engineered with capacitively coupled superconducting (SC) resonators arrays [26,27]. The specific realization of the qubit is flexible and platform-dependent. It can be achieved, for example, by a transmon within a purely superconducting setting [27,28,30,31] or by a quantum dot in the case of hybrid devices [29,32,33]. When both SSH chains are in the topologically non-trivial phase, i.e., inter-cell coupling \( w \) is larger than intra-cell coupling \( v \), we can observe two zero-energy modes localize at the edges in each array. The system in Fig. 2(a) is described by the Hamiltonian

\[
H = \sum_{i} \omega_{1,i} a_{1,i}^\dagger a_{1,i} + \sum_{<i,j>} J_{1,ij} a_{1,i}^\dagger a_{1,j} H_{\text{SSH},1} + \sum_{i} \omega_{2,i} a_{2,i}^\dagger a_{2,i} + \sum_{<i,j>} J_{2,ij} a_{2,i}^\dagger a_{2,j} H_{\text{SSH},2} + \frac{\omega_g}{2} \sigma_z + \xi_1 \sigma_x a_{1,N}^\dagger a_{1,N} + \xi_2 \sigma_x a_{2,1}^\dagger a_{2,1},
\]

where \( a_{X,i} \) are bosonic creation and annihilation operators in the SSH chains. \( X = 1,2 \) represents the two SSH chains and \( i \) indexes the lattice site number within a chain. The qubit is described by the operator \( \sigma_z = |e\rangle \langle e| - |g\rangle \langle g| \). We assume that the qubit is coupled to the resonators in the dispersive regime with \( \xi \) the qubit state-dependent dispersive frequency-shift of the resonators, given by \( \xi_X = g^2/\delta_X \), where \( g \) is the dipole-coupling between the resonator and the qubit. This assumption is valid when a large qubit-resonator detuning \( \delta_X \) with respect to the coupling strength \( g \) is present [26,27].

Within a rotation frame at \( \omega_1 = \omega_2 \) for the resonators and \( \omega_q \) for the qubit, we arrive at the following Hamiltonian:

\[
H = \sum_{<i,j>} J_{1,ij} a_{1,i}^\dagger a_{1,j} + \sum_{<i,j>} J_{2,ij} a_{2,i}^\dagger a_{2,j} + \xi_1 \sigma_x a_{1,N}^\dagger a_{1,N} + \xi_2 \sigma_x a_{2,1}^\dagger a_{2,1}.
\]

We start investigating the entanglement in the resonator-qubit system based on this Hamiltonian. A tripartite quantum state is created by exciting this system to a state that couples the qubit to the topological edge modes.
in both resonator arrays. By three parties, we here refer
to topological edge modes in first resonator array, the
to the qubit, and the topological edge modes in the second
resonator array. Below we show that the qubit projective
measurement results in a maximally entangled state
among the topological modes on SSH arrays, whose
robustness we wish to analyze.

We find eigenstates of the Hamiltonian Eq. (2) by ex-
act diagonalization. We proceed by performing projective
measurement in the \( \sigma_z \) basis on the qubit, thereby
projecting the qubit state either to the ground (\(|g\rangle\)) or
excited (\(|e\rangle\)) state. This projection yields number of pos-
sible entangled states between the remaining SSH arrays.
Below we elaborate on our calculation and entanglement
characterization.

In order to exact diagonalize Hamiltonian Eq. (3) on
the system shown in Fig. 2 we analyze the Hamiltonian
in the single excitation subspace of each SSH chain. The
basis is given by the tensor product of the three parties
of the system:

\[
\{|b_{full}\} = \{|b_{ssh1}\} \otimes |b_{qubit}\otimes |b_{ssh2}\}, \quad (4)
\]

with the basis of each SSH chain are given by

\[
\{|b_{ssh, X}\} = \\
\{|1,0,0,0,0,0,0\}, \{0,1,0,0,0,0,0\}, \\
\{|0,0,0,0,0,0,0\}, \{0,0,0,0,0,0,0\}, \\
\{|0,0,0,0,0,0,1\}, \{0,0,0,0,0,0,0\},
\]

where each digit represents a lattice site among the 8
sublattice sites. The qubit basis is given by

\[
\{|b_{qubit}\} = \{|e\rangle, |g\rangle\}. \quad (6)
\]

Therefore the Hilbert space size considered is \(8 \times 8 \times 2 = 128\).

The bipartite entanglement is achieved via the qubit
projection after preparing the system in an eigenstate.
The qubit projection operators are given by

\[
\hat{P}_e = \sum_{|b_{qubit}| = |e\rangle} \langle b_{full}|b_{full}\rangle, \\
\hat{P}_g = \sum_{|b_{qubit}| = |g\rangle} \langle b_{full}|b_{full}\rangle. \quad (7)
\]

The projection of the total 128 eigenstates onto two-qubit
states respectively yields 256 two-SSH states. Here, the
probability to measure the qubit state \(|e\rangle\) is 50%, simi-
larly for \(|g\rangle\) the probability is also 50%.

IV. ENTANGLEMENT STABILITY ANALYSIS

Negativity is a measure of bipartite quantum entan-
glement. It is derived from positive partial transpose
(PPT) criterion for separability of quantum states [38–
40]. Zero negativity values indicate no distillable en-
tanglement, while non-zero value characterizes the finite
amount of distillable entanglement. We use negativity to
characterize the entanglement generated in the scheme
presented above.

Consider a general system composed of two subsystems
A and B with a total density matrix \(\rho\). The total Hilbert
space is \(\mathcal{H}_A \otimes \mathcal{H}_B\) and the density matrix \(\rho\) is given by

\[
\rho = \sum_{ijkl} \rho_{ijkl} |i\rangle \langle j| \otimes |k\rangle \langle l|, \quad (8)
\]

\(\rho^{T_B}\) is the partial transpose of density matrix \(\rho\) with re-
spect to subsystem \(B\), given by [38–40]

\[
\rho^{T_B} := (I \otimes T)(\rho) = \sum_{ijkl} \rho_{ijkl} |i\rangle \langle j| \otimes |k\rangle \langle l||T

= \sum_{ijkl} \rho_{klij} |i\rangle \langle j| \otimes |k\rangle \langle l|,
\]

where \((I \otimes T)(\rho)\) is the identity map applied to the A
party and the transposition map applied to the B party.

Negativity can be computed through the absolute sum
of the negative eigenvalues of \(\rho^{T_A}\) [38–40], defined as the
following,

\[
N(\rho) = \left| \sum_{\lambda_i < 0} \lambda_i \right| = \sum_i \frac{|\lambda_i| - \lambda_i}{2}, \quad (10)
\]

where \(\lambda_i\) are all the eigenvalues of \(\rho^{T_A}\). Negativity is a
monotone and \(N \in [0,0.5]\) for bipartite entanglement.
Maximal entanglement states, such as Bell states, reach
the value \(N = 0.5\). Note that the negativity is independent
of which subsystem was partially transposed in
Eq. (3) since \(\rho^{T_A} = (\rho^{T_B})^T\).

Our proposed system indeed hosts states that lead to
the entanglement between two SSH chains. In Fig. 3, we
show the density matrix $\rho$ of one such $\mathcal{N} = 0.5$ state after the projection onto the $|e\rangle$ state. From the peaks in the density matrix it is shown that the amplitudes are located at the edges of the two arrays. We emphasize that in the two SSHs systems, each chain acts as a subsystem defined in Eq. (9). The entanglement measured by negativity is between two subsystems, i.e., between two entire SSH chains. However, given the number of eigenstates that the Hamiltonian Eq. (3) possesses, selecting the eigenstate that leads to maximal entanglement can be (experimentally) challenging. The selection feasibility will be addressed below.

In our stability analysis, the first step is to investigate the robustness of the entanglement against parameter fluctuations. To that end, the Hamiltonian Eq. (3) is prepared in the regime where both SSH arrays are in the topological phase. The hopping parameters $v, w$ have certain degrees of uncertainty which we numerically simulate by the random distributions. Exact diagonalization of a randomly sampled Hamiltonian yields its 128 eigenstates. For each eigenstate, we project out the qubit and evaluate the negativity $\mathcal{N}$ on the remaining two-SSH system.

Next, we identify the state with the highest negativity among all the eigenstates. In the topological regime, we find out that such highly entangled states occupy the edges of each chain, schematically shown in Fig. 4(a). In contrast, in the trivial regime, the maximally entangled state is distributed across the whole array, schematically shown in Fig. 4(b). Thus, we anticipate that the entanglement in the topological regime will remain stable against local parameter fluctuations since it shares the feature similar to the edge modes in the SSH model. On the other hand, the distributed nature of the maximally entangled modes in the trivial regime is expected to be strongly susceptible to fluctuations.

We quantitatively assess the robustness towards parameter fluctuations. We investigate the maximal negativity generated from 100 random Hamiltonians for each value of parameter fluctuation, $\delta$. Specifically, Hamiltonian hopping amplitude, given by value $v/w$, can fluctuate uniformly within the interval $[v - \delta/2, v + \delta/2]$ ($[w - \delta/2, w + \delta/2]$). In each Hamiltonian, all 128 eigenstates are projected to $|e\rangle$ qubit state without loss of generality, and the corresponding 128 negativities $\{\mathcal{N}\}$ are calculated. While we are displaying the results of projecting onto the $|e\rangle$ state, it is worth noting that projecting onto the $|g\rangle$ state yields similar results.

In the topological regime (upper panel of Fig. 4(c)) the maximal negativity $\text{Max}(\mathcal{N})$ distribution is centered around $\mathcal{N} = 0.5$. Additionally, this value remains robust with respect to increased parameter fluctuation $\delta$. In the trivial regime (lower panel of Fig. 4(c)) we observe that maximal negativity $\text{Max}(\mathcal{N})$ distribution changes rapidly with the parameter fluctuation and eventually decreases to zero. More importantly, the maximum negativity $\text{Max}(\mathcal{N})$ shows a large spread over the sampled Hamiltonians, for example, see the $\text{Max}(\mathcal{N})$ distribution at $\delta = 0.25\%$ in the lower panel of Fig. 4(c). In the trivial regime at the fixed parameter fluctuation, the fact that the maximal negativity varies for different samples indicates that after performing the measurement, the states collapse to more or less random states in the Hilbert space, and the structure of its correlations does not remain fixed. The resulting entanglement structure is discussed in App. C. We can conclude that the existence of $\mathcal{N} = 0.5$ entangled state is highly robust when the two SSH chains are in the topological regime, while the entangled state has a random negativity value and is prone to disorder in the trivial regime.

V. TARGETING THE MAXIMUM ENTANGLEMENT

In order to address the target topological entanglement state with $\mathcal{N} = 0.5$, such as in Fig. 4(a), we first study the energy spectrum of the system and the spectra change as a function of hopping parameter fluctuation. We show two eigenenergy spectra of Eq. (3) with parameter fluctuation $\delta = 1.0\%$ and $\delta = 10.0\%$ in the topological regime ($v = 0.1, w = 1.0$) in Fig. 5. The eigenstates are sorted
Statistical analysis of our simulations shows that the two states yielding maximum bipartite entanglement after projection (green triangles) frequently appear at the same eigenstate index of the non-disordered Hamiltonian. Thus we now investigate the eigenstate index stability to address the target maximum entanglement state. For instance, the non-disordered topological Hamiltonian of $\delta = 0.0\%$ shows maximal entanglement at eigenstate index 73 in the spectrum.

To keep the notation concise, we now refer to the eigenstate with index $|73\rangle$ as $|73\rangle$. We trace this state starting from zero $\delta$ ($\delta = 0.0\%$) towards large $\delta$ and calculate three quantities: the negativity, the fidelity between $|73\rangle$ and the target state $|\psi_73\rangle$ at disorder $\delta > 0$ and $|73_{\delta=0}\rangle$, and the energy difference between $|73\rangle$ at disorder $\delta > 0$ and $|73_{\delta=0}\rangle$, see Fig. 4. The fidelity between two states, $|\psi_a\rangle$ and $|\psi_b\rangle$, is evaluated as

$$F(a, b) = |\langle \psi_a | \psi_b \rangle|^2.$$  \hspace{1cm} (11)

Statistically, we choose a parameter fluctuation $\delta$ grid evenly from $[0.0\%, 2.0\%]$. For each $\delta$, we initialize 100 random Hamiltonians in the topological regime: $v = 0.1, w = 1.0$. As shown in Fig. 6 when parameter fluctuation $\delta$ grows beyond the threshold value (dashed vertical lines), the negativity distribution of $|73\rangle$ is no longer consistently at 0.5 and the mean value $\mathcal{N}$ decreases. Similarly the fidelity $F$ between $|73\rangle$ at zero $\delta$ and $|73\rangle$ deviates from $F = 1$ when passing the threshold $\delta$. Moreover we also see a drastic change in the log($\Delta E$) at threshold $\delta$. Note that the exact value of dashed vertical lines ($\approx 0.125\%$) is only to show the instability of the target state eigenindex. We can conclude from these studies that although the existence of a state that leads to a negativity $\mathcal{N} = 0.5$ is validated by Fig. 4, such states cannot be excited by simply addressing the specific eigenindex from the eigenspectra.

Despite the fact that the topological entanglement state cannot be directly identified by the eigenindex, we observe that the state is generally located within a certain energy window. We are interested in the probability

![FIG. 5. a) Eigenenergy spectrum with $\delta = 1\%$. b) Eigenenergy spectrum with $\delta = 10\%$. Both are in the topological regime ($v = 0.1, w = 1.0$). The two green upward and downward triangles represent the two maximally entangled states when the qubit is projected to $|c\rangle$ and $|g\rangle$, respectively. The middle near-zero-energy section in the spectrum (highlighted in orange) is enlarged in the right panel.](image)

![FIG. 6. Tracking the state $|73\rangle$ across the parameter fluctuation $\delta$. a) Negativity of state $|73\rangle$ projected to $|c\rangle$. b) Fidelity between the disordered $|73\rangle$ with respect to the target state $(|73\rangle$ at zero $\delta$ with known $\mathcal{N} = 0.5$). c) Logarithm energy difference between disordered $|73\rangle$ and the target state $(|73\rangle$ at zero $\delta$). Each dot represents a random Hamiltonian. At each parameter fluctuation $\delta$, 200 random Hamiltonians are generated. The color gradient shows the occurrence of negativity/fidelity at each value, i.e., the overlapping Hamiltonians. The Hamiltonians are in the topological regime with $v = 0.1, w = 1.0$. The vertical dashed lines indicate that the system undergoes a cross-over at a parameter fluctuation around $\delta = 0.125\%$.](image)
of locating the target state within such energy windows. The details of energy window preparation can be found in App. II. In the case of $v = 0.1, w = 1.0$, the energy window has size $\Delta_E = 1.08 \times 10^{-6}$ and centers around the target eigenenergy $E_{0,|e\rangle} = 9.9 \times 10^{-4}$ or symmetrically $E_{0,\langle e|} = -9.9 \times 10^{-4}$. The energy window parameters will change for different qubit projections as well as for different $v/w$ ratios. The complete parameters are given in Tab. I.

Generally in the topological regime, when a randomly disordered Hamiltonian has an eigenstate that leads to $N \neq 0$ states, there will only be one such state which is considered as the target state. When parameter fluctuation $\delta$ changes, the energy of this target state is stable in comparison to the scale of the width of the energy window.

When we address all the eigenstates within the prescribed $v/w$ dependent energy window, Figure 7 shows the mean negativity $\overline{\mathcal{N}}$ and the corresponding standard deviation. Each point is calculated from 100 random Hamiltonians and averaged from both qubit projections. We find that the mean negativity $\overline{\mathcal{N}}$ is stable at small $v/w$ ratios as in the upper panel of Fig. 7. The uncertainty rises as the $v/w$ increases from small $v/w$. Note here the increased $\delta$ does not increase the uncertainty in $\overline{\mathcal{N}}$. Thus, the topology of the SSH model is critical in stabilizing the entanglement.

Besides the mean negativity, we are also interested in the number of states within the energy window since the negativity is ill-defined in Fig. 8 if the energy window does not contain any state for a given Hamiltonian.

Specifically, we study the probability of having an energy window being non-empty, i.e., the energy window addressing at least one state of arbitrary $\mathcal{N}$, at various $\delta$ and $v/w$. In Fig. 8 each point is averaged over 100 random Hamiltonians. We find that when deep in the topological regime ($v/w = 0.1$), addressing the prescribed energy window will always hit a specific state, the negativity of which is shown in Fig. 7. In contrast, we find that the number of states within the target window decreases when the system moves away from deep topological regime, as shown in the case of $v/w = 0.2$ and 0.3. The probability of having a non-empty window also decreases with $\delta$ in the latter two cases. Overall, the topological entanglement can be systematically achieved by addressing the specific energy window for a random Hamiltonian deep in the topological regime ($v/w = 0.1$).

In this setup, the parameter fluctuation will not hinder the desired topological entanglement.

VI. CONCLUSION AND OUTLOOK

In this work, we proposed a protocol for realizing robust topological entanglement in superconducting circuits. Specifically, we theoretically construct a minimal architecture containing superconducting resonator arrays and a single qubit. We showed that the Bell-like entanglement between topological edge modes could be achieved by projecting out the qubit. Such entanglement is robust to parameter fluctuation in the resonator arrays. Additionally, we provided a detailed analysis of addressing the entanglement modes in the frequency space. We formulated a prescription on the rendered topologically stabilized entanglement as a function of parameter fluctuation. We conclude that there is always a unique way to prepare a maximally entanglement of topologically pro-

\end{figure}
ected edge modes by targeting a specific frequency window.

By proposing an experimentally accessible scheme for the proof of the principle of topology stabilized entanglement, we put forward the concept of classical metamaterial-inspired quantum devices engineering on firmly quantum footing. This work can be used as a stepping stone for further topology stabilized quantum information processing and communication. The potential applications include more robust quantum communications links or robust on-chip entanglement.

The code needed to reproduce the results presented in this manuscript can be found in [11].

Appendix A: SSH model spectrum

Given the SSH Hamiltonian Eq. (1), we analyze the topologically non-trivial case with hoppings $v = 0.5$, $w = 1.0$. The two topological edge modes are degenerate in the periodic boundary condition, while the degeneracy is lifted in the finite systems with open boundary condition.

In a lattice with $N = 16$ sites, the energy spectrum is given in left panel of Fig. 9. The two edge-states are shown in the middle of the gap. We find that the energy difference between two such mid-gap edge states increases when we move away from the deep topological non-trivial regime, i.e., small $v/w$ values. The degeneracy between two edge states is lifted when increasing $v/w$ in finite systems. The energy difference grows exponentially with respect to the $v/w$ ratio, as shown in the right panel of Fig. 9. This also indicates that the gap begins to close exponentially.

The experimental implementations of the SSH model can go beyond the fermionic systems. The photonic analog is realized in systems where superconducting qubits are coupled to a metamaterial waveguide [24]. The phononic analog is demonstrated in mechanical metamaterials [20]. More complicated 2D models with topological phases are also implemented using metamaterials [10] [42].

Appendix B: Analysis of entanglement at different $v/w$ ratio

In the presence of parameter fluctuation, the topological phase transition might happen at a different parameter value compared to ordered systems. Note the clear difference between maximal negativity distributions in the topologically non-trivial and trivial regime as shown in Fig. 4. The broadening of the distribution and decreasing of the mean value characterize the trivial phase. From the three panels with an increasing $v/w$ ratio, we find that although the system is still in the topological regime, the negativity distribution patterns show a crossover towards the trivial phase. Thus to address the target entanglement between topological modes, it is advised to stay deeply in the topological regime.

![FIG. 10. The maximal negativity $Max(N)$ vs parameter fluctuation $\delta$ under different $v/w$ ratio. The three panels are in the topological regimes.](image-url)
SSH1 and SSH2: edge-edge, edge-bulk, bulk-edge, and into four types according to their basis components of entanglements. We split the density matrix elements in this work. However, we can provide some insights into something goes beyond the bipartite entanglement.

Appendix C: Other type of entanglements

There exists some entanglement in the topological regime where the negativity exceeds 0.5, e.g., in the lower panel of Fig. 4(c). The fact that the negativity value should not exceed 0.5 means that this is an indication that something goes beyond the bipartite entanglement. We do not aim to fully understand such entanglements in this work. However, we can provide some insights into them.

In such a scenario, bulk also contributes to the entanglement. In this section, we briefly discuss such types of entanglements. We split the density matrix elements into four types according to their basis components of SSH1 and SSH2: edge-edge, edge-bulk, bulk-edge, and bulk-bulk. We illustrate this by starting from a state in topological regime with $N = 0.707$. The upper panel of Fig. 11 is the reduced density matrix with removed edge-edge components. It has negativity equals 0.671. Lower panel of Fig. 11 has removed bulk-bulk components with negativity = 0.658. The results show that the contributions from both the edge and bulk parts of the SSH are significant. This type of entanglement is complicated and beyond the scope of this work.

Appendix D: Energy window

In order to target the topological entanglement properly, we prepare an energy window in the following steps:

1. Step 1: Find out the target energies $E_{0, \text{qubit}}$ with the negativity $N = 0.5$ state when qubit is projected to either $|\text{qubit}\rangle = |e\rangle, |g\rangle$.

2. Step 2: Fix a trial energy window width $\Delta E$.

3. Step 3: Prepare an energy window centered at $E_{0, \text{qubit}}$ with width $\Delta E$ for both qubit projection states.

4. Step 4: Calculate $N$ for both qubit states.

5. Step 5: Investigate the target energy $E_{0, \text{qubit}}$ shift with respect to $v/w$ ratio.

The first step is to locate the target eigenenergies, i.e., eigenfrequencies. We sample 100 Hamiltonian among the grid of parameter fluctuation between $[0.0\%, 20.0\%]$. We filter out the state with $N = 0.5$ (rounded to 3 digits) and collect the specific one energy with minimal absolute value $E_{\text{sample, abs min}}$. We average the energy $E_{\text{sample, abs min}}$ over 100 Hamiltonian samples. Thus each $\delta$ grid has an energy value. We then choose the most representative energy according to the occurrence across the fluctuation grid. The most common energy is denoted as $E_{0}$. $E_{0}$ represents the mean energy of states with $N = 0.5$ ($N$ rounded to 3 digits).

In step 2 and 3, we prepare an energy window centered at $E_{0, \text{qubit}}$ corresponding to a practical experimental setup. The trial width is chosen to be the minimum energy difference between any two states lying on the middle spectrum sector in Fig. 5, i.e., the orange middle sector. The challenge here is such: if the energy window is too narrow, we might miss the target state. If the energy window is too broad, we will also excite unwanted states. The choice of energy window width is empirical and can be decided from numeric studies.

In step 4, we sample 100 Hamiltonian at each grid value in the $\delta$ grid. We calculate $N$ for all states lie in the energy window. The statistics on $N$ will characterize the probability of finding entangled topological states within this energy window as shown in Fig. 7 and Fig. 8.

The energy window we have used for the analysis in Fig. 7 and Fig. 8 is the Tab. 4 Note that the center of an energy window is relatively fixed for a specific $v/w$ ratio; the width can be adjusted to half size or double the size without losing the high targeting probability.

| $v/w$ | center, $|e\rangle$ | center, $|g\rangle$ | width  |
|-------|-------------------|-------------------|--------|
| 0.1   | $9.9 \times 10^{-4}$ | $-9.9 \times 10^{-4}$ | $1.08 \times 10^{-6}$ |
| 0.2   | $9.6 \times 10^{-4}$ | $-9.6 \times 10^{-4}$ | $4.50 \times 10^{-6}$ |
| 0.3   | $9.1 \times 10^{-4}$ | $-9.1 \times 10^{-4}$ | $2.87 \times 10^{-6}$ |
