Abstract

In statistical inference, uncertainty is unknown and all models are wrong. A person who makes a statistical model and a prior distribution is simultaneously aware that they are fictional and virtual candidates. In order to study such cases, several statistical measures have been constructed, such as cross validation, information criteria, and marginal likelihood, however, their mathematical properties have not yet been completely clarified when statistical models are under- and over-parametrized.

In this paper, we introduce a place of mathematical theory of Bayesian statistics for unknown uncertainty, on which we show general properties of cross validation, information criteria, and marginal likelihood. The derived theory holds even if an unknown uncertainty is unrealizable by a statistical model or even if the posterior distribution cannot be approximated by any normal distribution, hence it gives a helpful standpoint for a person who cannot believe in any specific model and prior.

The results are followings. (1) There exists a more precise statistical measure of the generalization loss than leave-one-out cross validation and information criterion based on the mathematical properties of them. (2) There exists a more efficient approximation method of the free energy, which is the minus log marginal likelihood, even if the posterior distribution cannot be approximated by any normal distribution. (3) And the prior distributions optimized by the cross validation and the widely applicable information criterion are asymptotically equivalent to each other, which are different from that by the marginal likelihood.

1 Introduction

Bayesian inference is now widely employed in statistics and machine learning, because it provides a precise predictive distribution when statistical
models and learning machines have hierarchical structures or hidden variables. In fact, the more complex statistical models are necessary in practical applications, the more important Bayesian inference becomes. This is the reason why mathematical foundation of Bayesian statistics is necessary for the cases when models and machines are under- or over-parametrized.

In an older Bayesian statistics of the 20th century, it was said that a person should have ability to capture an uncertainty by a statistical model and to represent a degree of belief by a prior distribution. Nowadays, however, we know the set of all probability distributions is so large that a person cannot believe in any specific one even for personal decision, which is often referred to as “all models are wrong” [8]. It was pointed out that a method how to determine or criticize a statistical model still remains unsolved [29].

In decision theory, coherent inference based on the subtle misspecification of a statistical model may take us to the wrong conclusion though it has been carefully prepared [7]. Hence, in Bayesian statistics, we need to check the predictive distribution and improve a model as sample size increases, in other words, strict coherency is incompatible with the world that uncertainty is unknown [15]. In the use of Bayesian statistics for scientific purpose, preparation of a model and a prior by a personal decision needs rethinking outside of a small world [19]. A new paradigm was proposed that both a statistical model and a prior distribution are candidate systems which had better be optimized for unknown data-generating process by mathematical procedures [1, 2, 3]. Based on these researches in the computer age [11], it was proposed that modern statistics is based on both computational algorithms and inferential evaluation, which has been accepted in statistics, data science, and machine learning fields.

In this paper, we introduce a place of mathematical foundation of Bayesian statistics for the case when uncertainty is unknown in a large world. That is to say, we study a case when a person, who makes a pair of a statistical model and a prior distribution, is simultaneously aware that it is only a fictional and virtual candidate. Needless to say, there is no completely objective evaluation method, however, it is possible to prepare a much wider set of probability distributions which contains a person’s choice as a special one and to examine a candidate pair from a more generalized point of view.

Statistical evaluation measures for unknown uncertainty have been proposed, for example, cross validation, information criteria, and marginal likelihood. However, their mathematical properties are not yet fully clarified because, if a statistical model has hierarchical structure or latent variables, the posterior distribution is highly singular. We clarify general theory when a statistical model is under- or over-parametrized, and show the following three mathematical properties.

First, although the leave-one-out cross validation [13, 27, 28] and information criterion [24] have the same asymptotic expectation values as the generalization loss, it is clarified that they have inverse correlation to the
generalization loss. Hence neither leave-one-out cross validation nor information criterion is the best estimator of the generalization loss. In this paper we show the better estimator can be made by using an adjusted sum of the leave-one-out and hold-out cross validations.

Second, we study the asymptotic behavior of the marginal likelihood when the posterior distribution is far from a normal distribution. If the posterior distribution can be approximated by some normal distribution, then the free energy, which is the minus log marginal likelihood, can be asymptotically approximated by BIC [25] whose variance term is given by the dimension of the parameter space. We show that, even if the posterior distribution contains singularities, the asymptotic expansion is given the real log canonical threshold. We study several methods how to estimate the free energy in such general cases.

Third, we compare the leave-one-out cross validation, the widely applicable information criterion, and the marginal likelihood as measures of a prior distribution. The optimal hyperparameter that minimizes the leave-one-out cross validation or the widely applicable information criterion converges to the optimal one that minimizes the average generalization loss, whereas the optimal hyperparameter that maximizes the marginal likelihood does not. Their equivalence and difference are studied theoretically and experimentally.

In section 2 we explain a place of mathematical framework of the Bayesian statistics when uncertainty is unknown. Two statistical measures, the free energy and the generalization loss are defined. Also the definition and meaning of the real log canonical threshold are introduced, which plays the central role in the theory of Bayesian statistics. In section 3 we explain the probabilistic properties of the generalization loss, leave-one-out cross validation, and widely applicable information criterion, and show the more precise measure of the generalization loss can be made. In section 4 the free energy or the minus log marginal likelihood is studied. In singular cases of over-parametrized models, they cannot be approximated by BIC, but can by new algebraic geometrical studies. In section 5 a prior optimization problem in a regular statistical model is analyzed. In sections 6 and 7 the results of this paper are discussed and concluded.

2 Mathematical framework of Bayesian statistics for unknown uncertainty

In this section, we introduce a mathematical framework of Bayesian statistics for a case when uncertainty is unknown.

Let $n$ be an arbitrary positive integer and $x^n = \{x_i \in \mathbb{R}^N ; i = 1, 2, \ldots, n\}$ be a set of real vectors. In this paper, we assume that a person, an agent, or an artificial intelligence makes a candidate pair of a statistical model $p(x|\theta)$
and a prior distribution $\pi(\theta)$, where $\theta \in \Theta$ is a parameter, such that

$$\theta \sim \pi(\theta), \quad (1)$$

$$x^n \sim \prod_{i=1}^{n} p(x_i|\theta). \quad (2)$$

Then the posterior and predictive distributions based on eqs.(1) and (2) are automatically defined by

$$p(\theta|x^n) = \frac{1}{p(x^n)} \pi(\theta) \prod_{i=1}^{n} p(x_i|\theta), \quad (3)$$

$$p(x|x^n) = \int p(x|\theta)p(\theta|x^n)d\theta, \quad (4)$$

where $p(x^n)$ is the marginal likelihood,

$$p(x^n) = \int \pi(\theta) \prod_{i=1}^{n} p(x_i|\theta)d\theta. \quad (5)$$

We study a case when a person is aware that a candidate pair $p(x|\theta)$ and $\pi(\theta)$ is a fictional and virtual one and wants to evaluate them from a more general standpoint. It is impossible to evaluate it from the completely objective point of view, however, we show that a much more objective place can be set than a specifically fixed pair. From eqs.(1) and (2), it follows that $x^n$ is exchangeable as shown by eq.(5). If $x^n$ is changeable, then by de Finetti’s theorem, there exist an unknown probability distribution $q(x)$ and an unknown functional probability distribution $Q$ such that

$$q(x) \sim Q(q), \quad (6)$$

$$x^n \sim \prod_{i=1}^{n} q(x_i). \quad (7)$$

Then the pair in eqs.(1) and (2) made by a person is a special case of the general set in eqs.(6) and (7). Hence, if a person who made eqs.(1) and (2) rejects the existence of eqs.(6) and (7), it is a mathematical contradiction. In other words, if a person prepares a statistical model $p(x|\theta)$ and a prior distribution $\pi(\theta)$, then $x^n$ is understood as a realization of a set of independent random variables $X^n$ whose probability distribution is unknown $q(x)$ which is subject to unknown $Q(q)$.

**Note.** A sample $x^n$ is understood to be from a real world, whereas a pair $p(x|\theta)$ and $\pi(\theta)$ is a fictional and virtual candidate prepared by a person. Both $q(x)$ and $Q(q)$ may be interpreted as also fictional and virtual concepts in a person’s mathematical mind, or an scientific assumption of date-generating process in the real world. It should be emphasized that the same
mathematical theory holds, independently of the assumption that \( q(x) \) and \( Q(q) \) are real or unreal, because mathematical framework is constructed for an arbitrary \( p(x|\theta) \), \( \pi(\theta) \), \( q(x) \), and \( Q(q) \). In both cases, if a pair \( p(x|\theta) \) and \( \pi(\theta) \) is provided, then the existence of \( q(x) \) and \( Q(q) \) is automatically derived. A person who cannot accept the existence of \( q(x) \) or \( Q(q) \) should reject the candidate pair \( p(x|\theta) \) and \( \pi(\theta) \). In this paper, we mainly study exchangeable cases. For cases when a sample is neither independent nor exchangeable, see subsection 6.2.

For an arbitrary function \( f(X^n) \) of \( X^n \), its expectation value for an unknown uncertainty \( q(x) \) is defined by

\[
E[f(X^n)|q] = \int f(x^n) \prod_{i=1}^n q(x_i) dx_i.
\]

The average and empirical entropies are respectively defined by

\[
S = -\int q(x) \log q(x) dx, \quad \text{(8)}
\]
\[
S_n = -\frac{1}{n} \sum_{i=1}^n \log q(X_i). \quad \text{(9)}
\]

Two well-known functionals of \((p, \pi)\), the free energy \( F_n = F_n(p, \pi) \) which is the minus log marginal likelihood, and the generalization loss \( G_n = G_n(p, \pi) \) are defined respectively by

\[
F_n = -\log \int \pi(\theta) \prod_{i=1}^n p(X_i|\theta) d\theta, \quad \text{(10)}
\]
\[
G_n = -\int q(x) \log p(x|X^n) dx. \quad \text{(11)}
\]

Then \( E[F_n|q] \) as a functional of \((p(x), \pi(\theta))\) is minimized if and only if the simultaneous Kullback-Leibler divergence

\[
\int q(x^n) \log \frac{q(x^n)}{p(x^n)} dx^n
\]

is minimized, where \( q(x^n) = \prod_{i=1}^n q(x_i) \). Also \( E[G_n|q] \) as a functional of \((p(x), \pi(\theta))\) is minimized if and only if the conditional Kullback-Leibler divergence

\[
\int q(x)q(x^n) \log \frac{q(x)}{p(x|x^n)} dx dx^n
\]

is minimized. These two properties show that both the average free energy and the average generalization loss can be employed as measures of appropriateness of the candidate pair given by eqs.\(10\) and \(11\) with respect to
the unknown information source \( q(x) \). Hence it is important to construct a mathematical theory of \( F_n \) and \( G_n \) which holds for arbitrary \( p(x|\theta) \), \( \pi(\theta) \), \( Q(q) \), and \( q(x) \). In general, for an arbitrary positive integer \( n \)

\[
\mathbb{E}[G_n|q] = \mathbb{E}[F_{n+1}|q] - \mathbb{E}[F_n|q]
\]

(12)

holds, however, minimization of the free energy gives the different result from that of the generalization loss.

For given probability distributions \( p(x|\theta) \) and \( q(x) \), two functions are defined by

\[
L(\theta) = -\int q(x) \log p(x|\theta) \, dx,
\]

(13)

\[
L_n(\theta) = -\frac{1}{n} \sum_{i=1}^{n} \log p(X_i|\theta).
\]

(14)

Let \( \Theta_0 \) be the set of all parameters that minimize \( L(\theta) \), and \( \theta_0 \) be an element of \( \Theta_0 \). In general, \( \Theta_0 \) consists of multiple elements and the Hessian matrix at \( \theta_0 \) is not positive definite. If \( \Theta_0 \) consists of a single element and the Hessian matrix at \( \theta_0 \) is positive definite, then \( q(x) \) is said to be regular for \( p(x|\theta) \), if otherwise singular. For example, in overparametrized models such as normal mixtures, neural networks, and many learning machines, \( \Theta_0 \) is an analytic or algebraic set with singularities [33]. In singular cases, the posterior distribution can not be approximated by any normal distribution even if \( n \) is sufficiently large. In this paper we assume that \( \Theta_0 \) consists of multiple elements in general and that \( p(x|\theta_0) \) does not depend on the choice of \( \theta_0 \in \Theta_0 \). Two variables \( L \) and \( L_n \) are defined by \( L = L(\theta_0) \) and \( L_n = L_n(\theta_0) \). For the case when \( p(x|\theta_0) \) depends on \( \theta_0 \in \Theta_0 \), see [21, 35]. If there exists \( \theta_0 \) such that \( q(x) = p(x|\theta_0) \), then \( q(x) \) is said to be realizable by \( p(x|\theta) \). If \( q(x) \) is realizable by \( p(x|\theta) \), then \( S = L \) and \( S_n = L_n \). The following concept RLCT is defined in both cases when \( q(x) \) is unrealizable by and singular for a statistical model \( p(x|\theta) \).

Definition of RLCT. For a given triple, \( (p(x|\theta), \pi(\theta), q(x)) \), a zeta function of Bayesian statistics is defined by

\[
\zeta(z) = \int (L(\theta) - L(\theta_0))^z \pi(\theta) d\theta,
\]

where \( z \in \mathbb{C} \) is one complex variable. If \( L(\theta) \) is a piecewise analytic function of \( \theta \), then \( \zeta(z) \) is a holomorphic function in the region \( \Re(z) > 0 \), which can be analytically continued to the unique meromorphic function on the entire complex plane [6, 18, 33]. It is proved that all poles of \( \zeta(z) \) are real and negative numbers. Let \( -\lambda \) \( (\lambda > 0) \) be the largest pole of \( \zeta(z) \) and \( m \) be its order. The constants \( \lambda \) and \( m \) are called the real log canonical threshold (RLCT) and multiplicity.
The concept RLCT is a well-known birational invariant in algebraic geometry, which plays an important role in Bayesian statistics. If \( q(x) \) is regular for a statistical model, then \( \lambda = d/2 \) and \( m = 1 \), where \( d \) is the dimension of the parameter space. For examples of RLCTs of singular statistical models, see subsection 6.1.

**Geometric Understanding of RLCT.** It has a clear geometric meaning. In fact, we can prove [33] that

\[
\lambda = \lim_{\varepsilon \to 0} \frac{\log \text{Prob}(\varepsilon)}{\log \varepsilon},
\]

where \( \text{Prob}(\varepsilon) \) is the probability of the set of almost optimal parameters measured by the prior distribution,

\[
\text{Prob}(\varepsilon) = \int_{L(\theta) < L(\theta_0) + \varepsilon} d\pi(\theta).
\]

Since this probability is equal to an invariant of singularities, the statistical estimation performance of the Bayesian inference is determined by a kind of volume dimension of an analytic or an algebraic set. Note that, the smaller the probability is, the larger RLCT is, since \( \log \varepsilon \to -\infty \). It was proved that, if \( 0 < \pi(\theta) < \infty \) on \( \Theta_0 \), then \( \lambda \) does not depend on the choice of \( \pi(\theta) \) and singularities in \( \Theta_0 \) make the probability larger than the regular points, hence RLCT smaller. If \( \pi(\theta_0) = 0 \) or \( \infty \) at \( \theta_0 \in \Theta_0 \) by controlling a hyperparameter, then \( \lambda \) depends on the hyperparameter. It may be an important fact that Jeffreys’ prior is equal to zero at singularities.

3 Cross Validation and Information Criterion

In this statistical inference about the generalization loss \( G_n \). Let us define a training loss \( T_n \), a leave-one-out cross validation loss (LOO) \( C_n \), and a widely applicable information criterion (WAIC) \( W_n \) respectively by

\[
T_n = -\frac{1}{n} \sum_{i=1}^{n} \log p(X_i | X^n), \quad (15)
\]

\[
C_n = -\frac{1}{n} \sum_{i=1}^{n} \log p(X_i | X^n \setminus X_i), \quad (16)
\]

\[
W_n = T_n + \frac{1}{n} \sum_{i=1}^{n} \nabla_{\theta} \log p(X_i | \theta), \quad (17)
\]

where \( p(x | X^n) \) is the predictive distribution defined by eq.14, \( X^n \setminus X_i \) is the sample leaving \( X_i \) out from \( X^n \), and \( \nabla_{\theta} \[ \] \) is the variance about \( \theta \) in the posterior distribution eq.13. Note that these functions are defined without using any information about \( q(x) \).
Then even if \( q(x) \) is not realizable by \( p(x|\theta) \) and even if \( q(x) \) is singular for \( p(x|\theta) \), the following properties are proved \([34, 38]\). Based on algebraic geometrical method, it was proved that there exist random variables \( R_1 \) and \( R_2 \) such that

\[
G_n = L + (\lambda + R_1 - R_2) \frac{1}{n} + o_p(1/n), \tag{18}
\]

\[
T_n = L_n + (\lambda - R_1 - R_2) \frac{1}{n} + o_p(1/n), \tag{19}
\]

\[
C_n = L_n + (\lambda - R_1 + R_2) \frac{1}{n} + o_p(1/n), \tag{20}
\]

\[
W_n = L_n + (\lambda - R_1 + R_2) \frac{1}{n} + o_p(1/n), \tag{21}
\]

where \( R_1 \) and \( R_2 \) satisfy \( \mathbb{E}[R_1] = \mathbb{E}[R_2] \) and

\[
R_2 = \frac{1}{2} \sum_{i=1}^{n} \psi(\theta)[\log p(X_i|\theta)] + o_p(1).
\]

Therefore both \( C_n \) and \( W_n \) are asymptotically unbiased estimators of \( G_n \), whereas neither AIC nor DIC \([26]\) is. Note that, if \( X^n \) is a set of independent random variables, then LOO and WAIC are asymptotically equivalent, if otherwise not. For the differences between LOO and WAIC, see subsection \([6]\).

These equations (18) - (21) show a good behavior of the leave-one-out cross validation and the widely applicable information criterion, however, \( G_n - L \) and \( C_n - L_n \) have an inverse correlation to each other,

\[
(G_n - L) + (C_n - L_n) = \frac{2\lambda}{n} + o_p\left(\frac{1}{n}\right).
\]

Also \( G_n - L \) and \( W_n - L_n \) satisfy the same equation \([34]\), which is the disadvantage of both LOO and WAIC. It should be emphasized that many statisticians may not be aware this weak point because it is not trivial from the definitions of LOO and WAIC. In this section we mainly study how to improve this advantage.

In order to overcome the disadvantage of LOO and WAIC, a more precise estimator can be made based on the theoretical results, eqs. (18)-(21). For a given two positive integers \( n_1 \) and \( n_2 \) such that \( n = n_1 + n_2 \), we divide a sample \( X^n = (X^{n_1}, X^{n_2}) \), where \( X^{n_1} = (X_1, X_2, \ldots, X_{n_1}) \) and \( X^{n_2} = (X_{n_1+1}, X_{n_1+2}, \ldots, X_n) \). The leave-one-out cross validation using \( X^{n_1} \) is

\[
C_{n_1} = -\frac{1}{n_1} \sum_{i=1}^{n_1} \log p(X_i|X^{n_1} \setminus X_i).
\]

Then it follows that

\[
\mathbb{E}[C_{n_1}] = L + \frac{\lambda}{n_1} + o(1/n_1).
\]
The hold-out cross validation or the out-of-sample cross validation is defined by
\[
H_{n_2} = -\frac{1}{n_2} \sum_{i=n_1+1}^{n} \log p(X_i|X^{n_1}),
\]
which estimates the generalization loss of the predictive distribution made by \(X^{n_1}\) that is measured by \(X^{n_2}\). This is an unbiased estimator of \(G_{n_1}\),
\[
\mathbb{E}[H_{n_2}] = L + \frac{\lambda}{n_1} + o_p(1/n_1).
\]
An adjusted cross validation (ACV) is defined by a weighted sum of the leave-one-out and the hold-out cross validations,
\[
A_n = \frac{n_1}{n} C_n + \frac{n_2}{n} H_{n_2},
\]
which shows \(A_n\) is an unbiased estimator of the generalization loss \(G_{n_1}\),
\[
\mathbb{E}[A_n] = L + \frac{\lambda}{n_1} + o(1/n_1).
\]
It follows that
\[
\frac{n_1}{n} \mathbb{E}[A_n - L_n] = \mathbb{E}[G_n - L] + o(1/n).
\]
which shows that \((n_1/n)(A_n - L_n)\) is an unbiased estimator of \(G_n - L\). Moreover, \(A_n - L_n\) does not have an inverse correlation to \(G_n - L\), hence it provides the better estimator than \(C_n - L_n\) and \(W_n - L_n\), if variables of \(1/n\) order are the main terms of the compared generalization loss. Note that, in the evaluation of prior distributions on the condition that a statistical model is fixed, then variables of \(1/n\) order are common, resulting that the adjusted cross validation may not be a better measure. See section 5.

Note that, if a probability distribution \(q(x)\) is realizable by \(p(x|\theta)\), then neither \(L = S\) nor \(L_n = S_n\) depends on \(p(x|\theta)\) and \(\pi(\theta)\). The rescaled hold-out or out-of-sample cross validation error
\[
\frac{n_1}{n}(H_{n_2} - L_{n_2}) = -\frac{1}{n} \sum_{i=n_1+1}^{n} \{\log p(X_i|X^{n_1}) - \log q(X_i)\}
\]
is also an unbiased estimator of \(G_n\), which has the larger variance than \(A_n\).

**Example 1.** In order to illustrate the differences of the several estimators of the generalization loss, a matrix factorization problem is studied. Let \(X\), \(A\), and \(B\) be \(M \times N\), \(M \times H\), and \(H \times N\) matrices respectively. A statistical model and a prior distribution of a matrix factorization are defined by
\[
p(X|A,B) \propto \exp\left(-\frac{1}{2}\|X - AB\|^2\right),
\]
\[
\pi(A,B) \propto \exp\left(-\frac{1}{2\rho^2}\|A\|^2 - \frac{1}{2\mu^2}\|B\|^2\right),
\]
where $\| \|$ is the Frobenius norm and $\rho, \mu > 0$ are hyperparameters. This model is sometimes employed for the purpose that a random matrix $X$ is estimated by a product of low rank matrices $A$ and $B$. Since the map $(A, B) \mapsto p(x | A, B)$ is not one-to-one, this model is not regular but singular. The posterior distribution cannot be estimated by any normal distribution.

The real log canonical threshold $\lambda$ of this model is same as that of the reduced rank regression which was clarified in [4]. In the experiment, we studied a case when $M = N = 8$, $\rho = \mu = 10$. A sample $X$ \text{\textit{n}} (n = 200) was taken from $q(X) = p(X|A_0, B_0)$ where $A_0 B_0 = \text{diag}(1, 1, 0, 0, 0, 0, 0, 0)$ is a diagonal matrix. Hence the rank of $A_0 B_0$ is $H_0 = 2$. We conducted two experiments $H = 2$ and $H = 6$. If $H = 2$, the model is appropriate for $H_0$, but if $H = 6$, the model is redundant. The values RLCTs for $H = 2$ and $H = 6$ are $\lambda = 14$ and $\lambda = 24$ respectively, whereas half of the dimensions of the parameter spaces $d/2 = (MH + HN - N^2)/2$ are 14 and 30, respectively. Two hundred independent trials were conducted. In experimental comparison, the average and empirical entropies of $q(X)$ are reduced from the estimators. Let the generalization error be $G.E. = G_n - S$.

The cross validation error, the widely applicable information criterion error, the adjusted cross validation error, the hold-out cross validation error, the AIC error, and the DIC [26] error are respectively defined by reducing the empirical entropy.

$$\text{CV.E.} = C_n - S_n,$$  \hspace{1cm} (26)

$$\text{WAIC.E.} = W_n - S_n,$$  \hspace{1cm} (27)

$$\text{AC.E.} = (n_1/n)(A_n - S_n),$$  \hspace{1cm} (28)

$$\text{HO.E.} = (n_1/n)(H_n - S_n),$$  \hspace{1cm} (29)

$$\text{AIC.E.} = \text{AIC} - S_n,$$  \hspace{1cm} (30)

$$\text{DIC.E.} = \text{DIC} - S_n.$$  \hspace{1cm} (31)

Note that AC.E. and HO.E. are estimators of $\mathbb{E}[G_{n_1}] - S$, they are used as estimators of $\mathbb{E}[G_n] - S$ by rescaling. In calculation of the adjusted and hold-out cross validations, we used $n_1 = n_2 = 100$. In Table 1, the five values from G. E. to HO. E. have asymptotically the same expectation value, $\lambda/n = 0.12$, whereas neither AIC nor DIC does, because matrix factorization is a singular statistical model and the posterior distribution cannot approximated by any normal distribution. In the table, MEAN and STD show averages and standard deviations of these random variables, and RSE shows the root square errors of the generalization error and estimated errors, $\mathbb{E}[(G.E. - \text{CV.E.})^2]^{1/2}$, $\mathbb{E}[(G.E. - \text{WAIC.E.})^2]^{1/2}$, and so on. These experimental results show the adjusted cross validation is a better estimator of the generalization loss than other estimators, because it has the smallest standard deviation and root square error in both cases $H = 2$ and $H = 6$.

### 4 Marginal Likelihood and Free Energy

In this section, several approximations of the free energy which is the minus log marginal likelihood eq(10) are compared. Even if $q(x)$ is not realizable by $p(x|\theta)$ or even if the posterior distribution cannot be approximated by any normal distribution, it is derived [33] that

$$F_n = n L_n + \lambda \log n - (m - 1) \log \log n + O_p(1),$$

where $\lambda$ and $m$ are RLCT and its multiplicity, respectively.

By eq.(12), the constant term of the free energy does not affect the generalization loss. In fact, the asymptotic balances of biases and variances are given by

$$E[F_n] = n L_n + \lambda \log n,$$

$$n \times E[G_n] = n L_n + \lambda,$$

hence the variance term $\lambda \log n$ of the free energy is larger than $\lambda$ of the generalization loss. In other words, optimizations for the free energy and the generalization loss are incompatible with each other. According to the increase of sample size $n$, this the different balance of the bias and variance affect the generalization performance [31].

In general, it needs heavy computational cost to calculate the numerical value of the free energy, hence several methods have been developed. If a statistical model is regular, then BIC [25] is defined by

$$\text{BIC} = n L_n(\hat{\theta}) + d \log n,$$

where $\hat{\theta}$ is the maximum likelihood estimator. The asymptotically main term of the free energy is given by

$$\text{Asymptotic} = n L_n(\hat{\theta}) + \lambda \log n.$$
In general, RLCT depends on \((q(x), p(x|\theta), \pi(\theta))\), this equation cannot be used directly if \(q(x)\) is unknown. The generalized version of BIC onto singular cases was proposed by using the estimated RLCT \(\hat{\lambda}\) \[10\],

\[
sBIC = nL_n(\hat{\theta}) + \hat{\lambda} \log n.
\]

This method sBIC needs theoretical results about RLCTs but does not need Markov chain Monte Carlo (MCMC) approximation of the posterior distribution. By using the MCMC sample of the parameter, another method was developed. A posterior distribution of the inverse temperature \(\beta > 0\) is defined by

\[
E^p(\beta)[f(\theta)] = \frac{\int f(\theta)\pi(\theta) \prod_{i=1}^{n} p(X_i|\theta)^\beta d\theta}{\int \pi(\theta) \prod_{i=1}^{n} p(X_i|\theta)^\beta d\theta}.
\]

Then WBIC is defined by \[36\]

\[
WBIC = E^p(1/\log n)[nL_n(\theta)],
\]

which satisfies

\[
WBIC = nL_n + \lambda \log n + o_p(\log n).
\]

Also it is proved that, if the posterior distribution can be approximated by a normal distribution, then

\[
WBIC = BIC + o_p(1).
\]

Note that BIC, Asymptotic form, and WBIC approximate the \(\log n\) order term of the free energy, hence their values have constant order differences from the free energy. The prior distribution does not affect their values directly if it does not change RLCT. It is well known that the posterior distribution of the mixture models can be numerically approximated by Gibbs sampler using latent variables, however, such a method can not be applied to the posterior distribution for general \(\beta > 0\). A new approximation method can be constructed to overcome this problem \[39\].

**Example.2.** Let us compare BIC, WBIC, and asymptotic form of the free energy. The asymptotic form is equal to sBIC if \(\hat{\lambda} = \lambda\). A matrix factorization problem same as Example.1 was studied. For \(M, N, H, H_0, n\) and \(A_0B_0\), the same condition as Example.1 was conducted. We compared Asymptotic/n - \(S_n\), BIC/n - \(S_n\), and WBIC/n - \(S_n\). Table \[2\] shows their averages and standard deviations. When \(H = H_0\), then three values coincided with each others, whereas in a singular case \(H > H_0\), then they were different. The experimental result shows that WBIC approximated the asymptotic from better than BIC in overparametrized cases.
\[
\begin{array}{|c|c|c|c|c|}
\hline
& H_0 = H = 2 & H_0 = 2, H = 6 \\
\hline
\text{Mean} & 0.3004 & 0.4792 \\
\text{Std} & 0.0190 & 0.0278 \\
\hline
\text{BIC} & 0.3004 & 0.6381 \\
\text{WBIC} & 0.3074 & 0.4918 \\
\hline
\end{array}
\]

5 Evaluation of Prior Distributions

In this section, we study the relation between prior distributions and generalization losses, on the assumption that a statistical model \( p(x|\theta) \) is regular and fixed, that is to say, for an arbitrary \( \theta \), the Hessian matrix of \( L(\theta) \) is positive definite.

We consider a condition that a candidate prior distribution \( \pi(\theta) \geq 0 \) may be improper, that is to say, in general,

\[
\int \pi(\theta) d\theta = \infty.
\]

Even if it is improper, the posterior and predictive distributions can be defined by eqs. (6) and (11) if both are finite. The generalization loss \( G_n(\pi) \), the leave-one-out cross validation \( C_n(\pi) \), the widely applicable information criterion \( W_n(\pi) \), the hold-out cross validation \( H_n(\pi) \), and the adjusted cross validation \( A_n(\pi) \) can also be defined by the same eqs. (11), (16), (17), (22), and (23), respectively. However, if a prior distribution is improper, the marginal likelihood cannot be a measure of the appropriateness of the prior distribution, because it may be made infinite by choosing an improper prior distribution.

In this section we fix a statistical model \( p(x|\theta) \) and study the effect of a candidate prior distribution \( \pi(\theta) \). The function \( q(x) \) is assumed to be unrealizable by a statistical model in general. Let \( \pi_0(\theta) > 0 \) be an arbitrary fixed nonnegative function on \( \mathbb{R}^d \). For example, one can choose \( \pi_0(\theta) \equiv 1 \) for an arbitrary \( \theta \). For a given \( (\pi(\theta), \pi_0(\theta)) \), a function \( \phi(\theta) \) is defined by

\[
\phi(\theta) = \pi(\theta)/\pi_0(\theta).
\]

On the foregoing assumptions, it is proved in [37, 38] that there exists a function \( M(\phi, \theta) \) such that

\[
\begin{align*}
\mathbb{E}[G_n(\pi)|q] &= \mathbb{E}[G_n(\pi_0)|q] + \frac{\mathcal{M}(\phi, \theta_0)}{n^2} + o\left(\frac{1}{n^2}\right), \quad (34) \\
\mathbb{E}[C_n(\pi)|q] &= \mathbb{E}[G_n(\pi_0)|q] + \frac{d/2 + \mathcal{M}(\phi, \theta_0)}{n^2} + o\left(\frac{1}{n^2}\right), \quad (35) \\
\mathbb{E}[W_n(\pi)|q] &= \mathbb{E}[G_n(\pi_0)|q] + \frac{d/2 + \mathcal{M}(\phi, \theta_0)}{n^2} + o\left(\frac{1}{n^2}\right), \quad (36)
\end{align*}
\]
where \( \theta_0 \) is the parameter that minimizes \( L(\theta) \) in eq. (13). That it to say, the expectation values of the generalization loss, the leave-one-out cross validation, and WAIC are equivalent in the higher order. Also it was proved in [37, 38] that there exists a function \( M(\phi, \theta) \) of \( \phi(\theta) \) and \( \theta \) which satisfies

\[
C_n(\pi) = C_n(\pi_0) + \frac{M(\phi, \hat{\theta})}{n^2} + o_p\left(\frac{1}{n^2}\right),
\]

(37)

\[
W_n(\pi) = W_n(\pi_0) + \frac{M(\phi, \hat{\theta})}{n^2} + o_p\left(\frac{1}{n^2}\right),
\]

(38)

where \( \hat{\theta} \) is the parameter that maximizes \( \pi_0(\theta) \prod_{i=1}^{n} p(X_i|\theta) \), in other words, \( \hat{\theta} \) is the maximum a posteriori estimator for a fixed prior function \( \pi_0(\theta_0) \). Hence LOO and WAIC are also equivalent in the higher order as random variables. The concrete forms of the functionals \( M(\phi, \theta) \) and \( M(\phi, \bar{\theta}) \) are defined by using higher order differential geometric forms of the log density function \( \log p(x|\theta) \) \[37, 38\]. They satisfy

\[
M(\phi, \hat{\theta}) = M(\phi, \theta_0) + O_p\left(\frac{1}{n^{1/2}}\right),
\]

(39)

\[
M(\phi, \mathbb{E}_{\theta}[\theta]) = M(\phi, \hat{\theta}) + O_p\left(\frac{1}{n}\right),
\]

(40)

\[
\mathbb{E}[M(\phi, \hat{\theta})] = M(\phi, \theta_0) + O\left(\frac{1}{n}\right).
\]

(41)

It should be emphasized that the generalization loss as a random variable has the different behavior from its own average,

\[
G_n(\pi) = G_n(\pi_0) + O_p\left(\frac{1}{n^{3/2}}\right).
\]

(42)

The parameter that minimizes the average generalization loss does not minimize the random generalization loss. Also minimization of WAIC or LOO by choosing \( \pi(\theta) \) makes the average generalization loss \( \mathbb{E}[G_n(\pi)] \) minimized asymptotically, however, it does not minimize the generalization loss \( G_n(\pi) \) as a random variable.

The free energy or the marginal likelihood has the different behavior than the cross validation and information criterion. Let \( F_n(\pi) \) be the free energy of a proper prior distribution. Assume that \( \pi(\theta) \) and \( \pi_0(\theta) \) satisfy \( \int \varphi(\theta)d\theta = \int \varphi_0(\theta)d\theta = 1 \). Then it follows that [41]

\[
F_n(\pi) = F_n(\pi_0) - \log \frac{\pi(\theta_0)}{\pi_0(\theta_0)} + o_p(1).
\]

(43)

\[
= F_n(\pi_0) - \log \frac{\pi(\hat{\theta}_{mle})}{\pi_0(\hat{\theta}_{mle})} + o_p(1),
\]

(44)

where \( \theta_{mle} \) is the maximum likelihood estimator. Hence the minimization of \( F_n(\pi) \) is asymptotically equivalent to maximization of \( \pi(\hat{\theta}_{mle}) \) at the maximum likelihood estimator.
If a set of candidate prior distributions is given by \( \{ \pi(\theta | a) : a \} \), where \( a \) is a hyperparameter, the optimal hyperparameter that is determined by minimization of \( F_n(\pi(\theta | a)) \) does not converge to the parameter that minimizes the average generalization loss in general even if the sample size tends to infinity.

**Example 3.** A simple polynomial regression is studied. Let \( x, y \in \mathbb{R} \) and \( f(x) \in \mathbb{R}^K \), and \( a \in \mathbb{R}^K \), where \( K \) is a positive integer. Using a function

\[
f(x) = (1, x, x^2, \ldots, x^{K-1})^T,
\]

a pair of a statistical model and a prior distribution is defined by

\[
p_k(y | x, a, s) = \left( \frac{s}{2\pi} \right)^{1/2} \exp \left( -\frac{s}{2} (y - a \cdot f(x))^2 \right), \tag{45}
\]

\[
\pi(a, s | b, c, d) \propto s^{b-1} \exp \left( -cs - \frac{ds}{2} \| a \|^2 \right). \tag{46}
\]

Note that the prior distribution is proper if and only if the hyperparameter \((b, c, d)\) satisfies \( b > K/2, \ c > 0, \ d > 0 \). Let \( q(x)q(y|x) \) be a data-generating distribution where \( q(x) \) is a standard normal distribution and \( q(y|x) = p(y|x, a_0, s_0) \) with \( a_0 = (1, -1/5, 1/30) \) and \( s_0 = 25 \). An experiment with \( K = 3 \) and \( n = 20 \) was conducted. The hyperparameter was set as \((b, c, d) = (b, 0.01, 0.01)\), where \( b = -3, -2.5, -2, \ldots, 6.5 \) are candidate hyperparameters. The optimal hyperparameter among them that minimizes \( \mathbb{E}[G_n(\pi)] \) is \( b = 0.5 \), which means the optimal one about \( b \) makes the prior distribution improper. Two hundred independent trials were conducted. The optimal hyperparameters for leave-one-out cross validation, widely applicable information criterion, adjusted cross validation, hold-out cross validation, and the free energy were chosen and the generalization errors for the chosen hyperparameters were recorded. Table 3 shows averages, standard deviation, and root square error of the optimized hyperparameters. Also the average and standard deviation of the corresponding generalization errors are shown.

The experimental results show that by the leave-one-out cross validation (LOO) and the widely applicable information criterion (WAIC), the optimal hyperparameter could be estimated, whereas by the other measures not. Note that the standard deviation of the chosen hyperparameters by WAIC is smaller than LOO. It would be helpful that minimization of the free energy is different from that of the generalization loss.

6 Discussion

In this section, we discuss two points of Bayes statistics.

#### 6.1 Real Log Canonical Threshold

In this subsection, we summarize researches about the real log canonical threshold (RCLT).

If \( q(x) \) is regular for \( p(x|\theta) \), then \( \lambda = d/2, m = 1, \) and \( R_2 = \text{tr}(IJ^{-1})/2 \) in eq. (11), where \( d \) is the dimension of the parameter space, \( I \) and \( J \) are the Fisher information matrix at \( \theta_0 \) and the Hessian matrix of \( L(\theta) \) at \( \theta_0 \), respectively. If \( q(x) \) is regular for and realizable by \( p(x|\theta) \), then \( 2R_1 \) is a random variable whose probability distribution is \( \chi^2 \) distribution with \( d \) degrees of freedom, and \( R_2 = d/2 \).

If a statistical model contains hierarchical structure or hidden variable, then it is in general singular. Such a statistical model is often prepared sufficiently large so that it can approximate unknown information source, hence RLCTs in overparametrized cases are important in model evaluation.

The concrete values of RLCTs of singular statistical models have been clarified, for example, reduced rank regressions [4], neural networks [5, 31], normal mixtures [44], Poisson mixtures [24], Latent Dirichlet allocations [17], and multinomial mixtures [42]. It is also clarified that, based on RLCT, the exchange probability of exchange MCMC methods can be optimally designed [20]. The mean field approximation of the posterior distribution is called the variational Bayesian inference. Both the generalization loss and the free energy of the variational Bayes are clarified [30, 22], which are different from Bayesian cases.

#### 6.2 Comparison of Cross Validation and Information Criterion

In this subsection, we compare cross validation and information criterion from theoretical and computational points of view.

First, we compare cross validation and information criterion in not i.i.d. cases. If a sample is i.i.d. or exchangeable, then leave-one-out cross validation (LOO) and WAIC are asymptotically equivalent, if otherwise not. For example, in a regression problem where the conditional probability density
\(q(Y_i|X_i)\) is estimated, \(\{X_i\}\) may be independent, fixed, or time-dependent. If \(\{(X_i, Y_i)\}\) are independent, the generalization loss is defined by the same way as eq.(11), resulting that LOO and WAIC are asymptotically equivalent. If \(\{Y_i|X_i)\}\) are independent but \(\{X_i\}\) are not independent, the generalization loss is different from eq.(11), which can be estimated by WAIC not by LOO. This difference becomes large if the leverage sample point is contained or the dimension of inputs \(\{X_i\}\) is high [39]. Hence, for the cases when \(\{Y_i|X_i)\}\) are independent, then the adjusted cross validation eq.(23) should be defined by the replacement of \(C_{n_1}\) by \(W_{n_1}\). For general dependent cases such as time sequence analysis, the evaluation methods of the statistical models and prior distributions are not yet fully constructed, however, several measures which contain a specific statistical model, for example, the leave-future-out cross validation, were proposed [9].

Second, we study computational problems of cross validation and information criterion. In Bayesian inference, calculation of the leave-one-out cross validation needs heavy computational costs because the posterior distributions for \(X^n \setminus X_i\) is necessary for all \(i = 1, 2, ..., n\). The importance sampling cross validation

\[
\text{ISCV} = \frac{1}{n} \sum_{i=1}^{n} E_\theta[\log(1/p(X_i|\theta))] \quad (47)
\]

can be used for numerical approximation. If a leverage sample point is contained a sample, the posterior average or variance may be infinite citeEpifani,Perugia, and a new estimation method has been proposed which are useful in many practical problems [27, 28].

7 Conclusion

We introduced a place of mathematical theory of Bayesian statistics when uncertainty is unknown. In almost all cases, a person who makes a pair of a statistical model and a prior distribution is aware that it is a fictional and virtual candidate. Therefore, a person needs statistical evaluation measures which can be employed even if an uncertainty is unrealizable or singular for a statistical model. Mathematical theory of a cross validation, an information criterion, and a marginal likelihood will be one of the most important foundation for Bayesian statistics for unknown information source.
