Adversarial Robustness of Graph-based Anomaly Detection

Yulin Zhu, Yuni Lai, Kaifa Zhao, Xiapu Luo, Mingquan Yuan, Jian Ren, Kai Zhou

Abstract—Graph-based anomaly detection is becoming prevalent due to the powerful representation abilities of graphs as well as recent advances in graph mining techniques. These GAD tools, however, expose a new attacking surface, ironically due to their unique advantage of being able to exploit the relations among data. That is, attackers now can manipulate those relations (i.e., the structure of the graph) to allow target nodes to evade detection or degenerate the classification performance of the detection. In this paper, we exploit this vulnerability by designing the structural poisoning attacks to a FeXtra-based GAD system termed OddBall as well as the black box attacks against GCN-based GAD systems by attacking the imbalanced lienarized GCN (LGCN). Specifically, we formulate the key technical challenge is to efficiently solve the problem in a discrete domain. We propose a novel attack method termed BinarizedAttack based on gradient descent. Comparing to prior arts, BinarizedAttack can better use the gradient information, making it particularly suitable for solving discrete optimization problems, thus opening the door to studying a new type of attack against security analytic tools that rely on graph data.

Index Terms—Graph-base anomaly detection, Graph learning and mining, Data poisoning attack, Adversarial machine learning, Discrete optimization

1 INTRODUCTION

Anomaly detection is a long-standing task in the field of data science and engineering with the goal to spot unusual patterns from the massive amount of data. Recently, due to the powerful representation abilities of graphs as well as the advances in graph mining and learning techniques, Graph-based Anomaly Detection (GAD) is becoming prevalent across a wide spectrum of domains. Various GAD systems are proposed and deployed as an indispensable security component in detecting, for example, fake accounts in social networks [1], fraudulent transactions in the financial industry [2], and Botnets in communication networks [3].

Those GAD systems, however, expose a new attacking surface, ironically due to their unique advantage of being able to exploit the connections among data (i.e., edges in graphs). As a motiavative example, consider the problem of misinformation diffusion in social networks, where an attacker aims to identify a set of nodes as the sources (called seeds) to diffuse misinformation (e.g., fake news or hate speeches) through social media platforms. To maximize the diffusion range, the attacker can employ some influence maximization [4] algorithms to identify those most promising seeds, which however are prone to be labeled as anomalous by GAD systems. Meanwhile, the attacker can proactively alter the social ties (e.g., friend/unfriend with other users) of those seeds so as to prevent them from being detected. That is, attackers now can evade GAD systems via manipulating the structure of the graph; we term such attacks as structural attacks. In Fig. 1 we demonstrate how our proposed structural attacks can help those seeds to evade a popular GAD system.

The previous example shows that there is an urgent need to investigate the adversarial robustness of current GAD systems – how robust could those GAD systems be under carefully designed attacks? To this end, we initiate the study of structural attacks against GAD systems, answering to what extend an attacker can evade the detection of prevalent GAD systems by solely manipulating graph structures. Studying such structural attacks has significant practical implications. Previous research on evading detection tools (e.g., PDF/Android malware detection [5]) primarily operate in a feature space, where attackers manipulate the extracted feature vectors. Consequently, it is known that the manipulated feature vectors are hard to be mapped back to real entities (e.g., PDF/Android software), affecting the effectiveness of the actual attacks. In contrast, altering the structure of a graph always corresponds to manipulating actual connections among entities, making structural attacks highly realizable in practice. Besides, there are scenarios...
where an attacker could have control of the whole graph structure, allowing the global optimization of the attacks. A representative example is the Command & Control center in Botnets [3], which can coordinate the communication among Bots, i.e., globally optimizing the structure of the communication graph, to evade Botnets detection tools. These practical threats imposed by structural attacks motivate us to systematically study the attacker’s ability to evade GAD.

In this paper, we instantiate our study by attacking two families of widely used GAD systems. The first family is termed as FeXtra-Based GAD systems. Specifically, these systems (e.g., OddBall [6]) extract structural features of each node in the graph, then build regression models over those features, and finally compute the node anomaly scores. We focus on FeXtra-Based GAD systems, particularly OddBall, mainly due to the following reasons. First, OddBall stands for a class of simple while effective approaches that require much less information from data, and thus are widely adopted in practice. Second, the hand-crafted features in OddBall are based on domain-specific knowledge, which well captures the endogenous structural anomalous in the graph. In comparison, the second family relies on the ability of Graph Convolutional Networks (GCNs [7]) as the essential component to automatically learn the anomalous patterns, thus termed as GCN-based GAD systems. Since GCNs are demonstrated to achieve state-of-the-art performances across various graph-related tasks, we also choose them as our attack targets.

However, attacking GAD systems faces several challenges. First, GAD systems naturally feature an unsupervised/semi-supervised setting, where all nodes reside in a single graph. Attacking GAD thus is poisoning the data from which the detection model is built, which is in strong contrast to those attacks that are manipulating the inputs to a fixed trained model. These poisoning attacks are mathematically modeled as bi-level optimization problems, which are notoriously hard to solve in the literature. Second, structural attacks operate in a discrete domain, resulting in a strategy space exponential in the graph size. Furthermore, the discrete nature makes it hard to adopt gradient-descent-based attack methods [8], [9], as the attacker now needs to make binary decisions on deleting or keeping the connections in the graph. Indeed as we will show later, trivially utilizing the gradient information may result in non-effective attacks.

To tackle these challenges, we propose BinarizedAttack, which is inspired by Binarized Neural Networks (BNN) [10] designed for model compression. Specifically, BNN transforms the real-valued model weights to discrete values $+1/-1$ to reduce the model size. To find the discrete optimal weights, BNN uses a continuous version of the weights when computing the gradients in the backward propagation. In light of this, BinarizedAttack associates a discrete as well as a continuous decision variable for each edge/non-edge in the graph and uses a novel gradient-descent-based approach to solve the resulting discrete optimization problem. Specifically, in the forward pass, the discrete decision variables are used to evaluate the objective function. In the backward pass, the continuous decision variables are firstly updated based on the fractional gradients, and the discrete ones are then updated accordingly. In essence, BinarizedAttack could better use the gradient information to guide the search for the optimal graph structure. Comprehensive experiments demonstrate that BinarizedAttack can effectively solve the discrete optimization problem and outperforms other gradient-descent-based approaches.

In summary, we identify and initiate the study of a new vulnerability of graph-based anomaly detection systems. Our results show that by slightly modifying the graph structure, attackers can successfully evade two families of widely used GAD systems. In particular, we propose a novel gradient-descent-based approach BinarizedAttack that can effectively solve discrete optimization problems, outperforming existing methods. The research opens the door to studying this new type of attacks against graph-based learning systems.

2 RELATED WORKS

2.1 Graph-based anomaly detection

The essential task of Graph-based Anomaly Detection (GAD) is to identify anomalous patterns from graph data. It becomes prevalent due to the powerful representation ability of graphs as well as the advances in graph mining and learning techniques. Our focus is anomaly detection on static graphs [11], where the graph structure and node features are fixed overtime. Representative GAD can be roughly classified into four classes. Specifically, feature-based methods [6] extract hand-crafted features from the graph and use typical machine learning approaches to analyze those features. Proximity-based methods [12] exploit the graph structure to measure the distances among nodes and anomalous nodes are assumed to have larger distances to other nodes. Community-based methods [13] employ community detection approaches to cluster normal nodes. Relational-learning-based methods [14] design graphical models to capture the relations among nodes and cast anomaly detection as a classification problem. Importantly, all these methods rely on the graph structure as an essential input. More recently, there are methods based on the powerful graph neural network to capture anomalous features in the relational data [15], [16], [17], [18], the propagation of the convolutional layer naturally can distinguish the anomalous relation information of the anomaly nodes among the benign nodes.

2.2 Adversarial graph analysis

Our work belongs to a long line of research that studies the adversarial robustness of various graph analysis tasks, such as node classification [8], [9], [19], link prediction [20], [21], community detection [22], etc. All related works on attacking graph analytic tools ( [8], [9], [19], [20], [21], [22]) formulate the structural attacks as discrete optimization problems. Those approaches for solving the optimization problems diverge into two categories: task-specific and general. The task-specific approaches heavily rely on the concrete scenarios of the optimization problem, which of course depends on the target model. For example, [20] studies the sub-modularity of the objective functions and accordingly proposes an approximation algorithm with nice theoretical guarantees. In contrast, the
general approach is to use the gradient-descent method to optimize the objective iteratively. The key to this approach lies in properly using the gradient information to guide the optimization process in the discrete process. The most notable representative is a greedy approach wherein each iteration the edge corresponding to the largest gradient is selected (thus *greedy*) to alter. For example, [9] generates the adversarial perturbations on both the node features and graph structure by maximizing the classification margin of the target nodes and make the decision by greedy search; [9] utilizes the meta-gradient on the bi-level optimization problem of the structural poisoning attack on node classification. Our proposed BinarizedAttack differs in the way of utilizing the gradient information by using two sets of discrete and continuous variables in optimization, which will lead to more precise updates in the discrete space. This idea of using two sets of variables is loosely connected to binary neural networks [10], which feature binary network parameters with a rather different design goal of making the size of the neural network compact. In fact, we adapted the greedy approach to our case, resulting in a strong baseline attack method termed GradMaxSearch. We analyzed the advantages of BinarizedAttack compared to GradMaxSearch in Section 5.2 and our comprehensive experiments also demonstrated that BinarizedAttack outperforms GradMaxSearch on all datasets.

3 Background on GAD Systems

In this section, we provide the necessary background on the two families of GAD systems – one based on feature extractions and the other based on GNNs.

3.1 FeXtra-Based GAD Systems

We introduce OddBall [8] as one of the representative Feature eXtraction (FeXtra for short) based GAD systems that we aim to attack. At a high level, OddBall extracts some carefully crafted structural features for each node in the graph, and computes an anomaly score for each node based on those features, where a larger score indicates that the node is more likely to be abnormal.

To formalize, we denote a graph as \( G = (V, E) \), where \( V \) denotes a set of \( n \) nodes and \( E \) represents the edges. We consider a simple unweighted graph with the adjacency matrix \( A \in \{0, 1\}^{n \times n} \). OddBall focuses on the local structural information of the nodes for anomaly detection. Specifically, for a node \( v_i \in V \), OddBall examines an Egonet ego, centered at \( v_i \), where ego\( _i \) is the reduced sub-graph contains \( v_i \) and its one-hop neighbors. An important finding of OddBall is that the Egonets for anomalous nodes tend to appear in either a near-clique or near-star structure (as shown in Fig. 2a). To detect such anomalous structures, OddBall identifies two critical features \( E_i \) and \( N_i \) among others from the Egonet ego\( _i \), where \( E_i \) and \( N_i \) denote the number of edges and nodes in ego\( _i \), respectively. It was observed that \( E_i \) and \( N_i \) follow an Egonet Density Power Law [8]: \( E_i \propto N_i^{\alpha}, 1 \leq \alpha \leq 2 \). The nodes that significantly deviate from this law are thus flagged as anomalous.

OddBall uses a regression-based approach to quantify the deviation. Specifically, let vectors \( \mathbf{E} = (E_1, E_2, \cdots, E_n) \) and \( \mathbf{N} = (N_1, N_2, \cdots, N_n) \) be the collected features of all nodes. Based on the power law observation, one can use the following linear model to fit the pair of features \( (E_i, N_i) \) for a node \( i \):

\[
\ln E_i = \beta_0 + \beta_1 \ln N_i + \epsilon.
\]

In the above equation, the model parameters \( \beta_0 \) and \( \beta_1 \) are given by the Ordinary Least Square (OLS) estimation:

\[
[\beta_0, \beta_1] = ([1, \ln N_i]^T [1, \ln N_i]^{-1}) (1, \ln N_i^T \ln E_i),
\]

where \( 1 \) is an \( n \)-dimensional vector of all 1’s.

The anomaly score \( S_i(A) \) for the node \( v_i \) is then computed as

\[
S_i(A) = \frac{\max(E_i, e^{\beta_0} N_i^{\beta_1})}{\min(E_i, e^{\beta_0} N_i^{\beta_1})} \ln(|E_i - e^{\beta_0} N_i^{\beta_1}| + 1).
\]

Note that we made the dependency of \( S_i(A) \) on \( A \) explicit as all of \( \beta_0, \beta_1, E_i, N_i \) rely on \( A \). As illustrated in Fig. 2b, the anomaly score \( S_i(A) \) intuitively measures the distance between the point \((N_i, E_i)\) and the regression line along the vertical axis. Finally, nodes with high anomaly scores (e.g., by ranking) are determined as anomalous by OddBall.

3.2 GCN-Based GAD Systems

With the advances of graph neural networks, an increasing number of GAD systems are using GCN [7] as the backbone for automatically learning useful anomalous patterns. In essence, anomaly detection is cast as a supervised classification process where the labels of a portion of nodes are provided for training. Specifically, GCN-based methods will take as input an attributed graph where nodes are associative with feature vectors, and generate node embeddings through several convolutional layers as follows:

\[
H^{t+1} = \sigma(\hat{A}H^tW),
\]

\[
\hat{A} = \text{diag}(\sum_{i=1}^{n} A_i)^{-\frac{1}{2}}(A + I)\text{diag}(\sum_{i=1}^{n} A_i)^{-\frac{1}{2}}
\]

\[
H^0 = \sigma(\hat{A}XW).
\]

In the above, \( A \) and \( X \) are the adjacency matrix and feature matrix, respectively; \( W \) summarizes the learned model parameters; \( H^t \) are the learned embeddings through the layers. Finally, the embeddings are fed into a fully connected layer for classification. The specific methods in this family integrate some minor modifications into this framework to adapt to the various application scenarios that they are...
designed for. In the following, we introduce six typical GCN-based GAD systems and highlight their differences:

- **GCN-reweight** [2]. This is the GCN model with class-specific loss weight to mitigate the imbalance problem. It assigns higher weight loss for the minority class.
- **GAT-reweight** [24]. This is the GCN model augmented with the graph attention mechanism to automatically distinguish the contributions from different neighbors in the aggregation phase. Similar to the GCN-reweight, it assigns higher weight loss for the minority class.
- **FdGars** [15]. It utilizes GCN for fraudulent detection in the online APP review system to distinguish the malicious users out of benign users.
- **GEM** [16]. It is the first heterogeneous graph neural network model to detect anomalous accounts at Alipay. It also augments the attention mechanism to control the contributions from different nodes, and utilizes EM algorithm to iteratively update the node embeddings and model parameters.
- **Player2vec** [17]. It is specially designed to detect the cybercriminals in the e-commerce system by adopting GCN augmented with the attention mechanism to automatically capture the anomalous behaviors in the environment.
- **GraphSMOTE** [18]. GraphSMOTE adopts synthetic minority oversampling techniques (SMOTE) to generate an augmented graph to mitigate the class imbalance problem in the bot detection field by using the synthetic node generator and edge generator to interpolate new synthetic nodes and edges for the minority class. Then the GCN classifier is implemented on the augmented graphs for imbalanced node classification.

4 Formulation of Attacks

4.1 Threat Model

We consider a system consisting of three parties: a defender, an attacker, and the outside environment, the interplay among which is illustrated in Fig. 3. Specifically, a defender deploys a GAD system to detect anomalous nodes in an existing network. In practice, the network is not readily available; instead, the defender will need to construct the network via data collection. We model data collections as a querying process where the defender sends queries consisting of pairs of nodes \((u, v)\) to the environment, which responds with the existence of the relation between \(u\) and \(v\) (i.e., whether there is an edge between \(u\) and \(v\)). Then, based on the query results the defender can construct an observed network. This querying process models real-world scenarios such as taking surveys on friendships, conducting field experiments to measure the communication channels, etc.

An attacker, sitting between the defender and the outside environment, can tamper with the above data collection procedure by modifying the query results sent from the environment. For example, as shown in Fig. 3, the defender makes a query “Is there a relation between \(C\) and \(D\)” to the environment; an attacker can change the query result \(\{C, D\} = 0\) (non-existence) to \(\{C, D\} = 1\) (existence), which is obtained by the defender. Consequently, the attacker is inserting an edge in the network constructed by the defender. That is, by modifying the query results, the attacker is equivalently manipulating the network topology, resulting in structural attacks. We state the attacker’s goal, knowledge, and capability as follows.

- **Attacker’s Goal.** For attacking unsupervised learning approaches like OddBall, we assume that the attacker has a set of target nodes within the network, which are risky nodes that have relatively high anomaly scores initially. The attacker’s goal is thus to enable these target nodes to evade the detection. For attacking supervised learning methods such as GCN, the attacker’s goal is to minimize the overall classification accuracy of the GAD systems.
- **Attacker’s Knowledge** We assume a worst-case scenario where the attacker has full knowledge of the network structure. That is, the attacker knows all the queries as well as the results to all those queries. Regarding the deployed GAD systems, we consider different cases where the attacker may or may not know the exact model in deployment.
- **Attacker’s Capability.** Again, we consider a worst-case scenario where the attacker can modify the query results at her choice. That is the attacker has control of the global structure of the graph and is able to add/delete edges from the graph. To further constrain the attacker’s ability, we assume that the attacker can add/delete up to \(B\) edges.

4.2 Problem Formulation

In this section, we first universally formulate the structural poisoning attacks against various GAD systems as bi-level discrete optimization problems. Then, we instantiate the attack problems against OddBall and GCN-based methods, respectively, based on their unique characteristics.

We use \(G_0 = \{V_0, E_0, X_0, Y_0\}\) to represent the ground-truth graph in the environment, where \(Y_0\) are the binary (anomalous or not) labels of the nodes. In particular, \(X_0 \in \mathbb{R}^{n \times p}\) denotes the attribute matrix for the nodes, where each node has an attribute vector of dimension \(p\). When the node attributes are not available, we set \(X_0 = \emptyset\). In structural attacks, the attacker will manipulate the graph structure in the data collection phase, resulting in a manipulated graph.
$G = \{V_0, E, X_0, Y_0\}$ observed by the defender. We note that only the graph structure $E_0$ will be modified to $E$. We use $A_0$ and $A$ to denote the adjacency matrices of $G_0$ and $G$, respectively. Then the structural poisoning attacks against the GAD systems can be formulated as:

$$A^* = \arg \min_A \mathcal{L}_{atk}(A, X, \theta^*, Y),$$

s.t. $\theta^* = \text{Regression}(A, X, \theta, Y)$,

$$\frac{1}{2} \|A_0 - A\|_1 \leq B, \quad A \in \{0, 1\}^{n \times n}.$$  

(5a)

Here, in (5a) the loss function $\mathcal{L}_{atk}(\cdot)$ quantifies the attacker’s malicious goal of evading detection. In (5b), we use $\text{Regression}(\cdot)$ to denote the training process of a GAD system, where the output is the optimal model parameter $\theta^*$ by specially designed regression methods. (5c) specifies the budget constraint on the attacker’s power. We emphasize that we solve the complex bi-level optimization problem where whenever one tries to optimize graph structure $A$, the optimal model parameter $\theta^*$ would change according to a complex training process to the one-level case by finding an appropriate point estimation $\theta^*$ for different scenarios.

### 4.2.1 Attacking FeXtra-Based GAD Systems

We now formulate the attacks against FeXtra-Based GAD systems with OddBall as an instantiation. We assume that the attacker has a set of target nodes $T \subset V_0$, and her goal is to reduce the probabilities that the nodes in $T$ are detected as anomalous. To this end, the attacker is allowed to add or delete at most $B$ edges in the graph $G_0$ with the goal of minimizing the anomaly scores of the target nodes in $T$. In our formulation, we consider the weighted sum of $S_T(A) = \sum_{v_i \in T} \kappa_i S_i(A)$.

$$\tilde{S}_T(A) = \max_{v_i \in T} \frac{\ln(E_i)}{\ln(N_i)} + 1, \quad S_i(A) = \frac{\ln(E_i)}{\ln(N_i)} + 1, \quad S_i(A) = \frac{\ln(E_i)}{\ln(N_i)} + 1,$$

$$\tilde{S}_T(A) = \max_{v_i \in T} \frac{\ln(E_i)}{\ln(N_i)} + 1, \quad S_i(A) = \frac{\ln(E_i)}{\ln(N_i)} + 1$$

where $S_i(A)$ denotes the anomaly score of node $v_i$ and $(\beta_0, \beta_1)$ is the optimal parameters of the regression model. For simplicity, in this paper, we consider the equal weight case, i.e., $\forall i, \kappa_i = 1$; however, our methods can be easily extended to the case with unequal weights. Then the attack can be formulated as the following optimization problem:

$$A^* = \arg \min_A S_T(A),$$

s.t. $\beta_0^*, \beta_1^* = \text{Train}(A),$

$$\frac{1}{2} \|A_0 - A\|_1 \leq B, \quad A \in \{0, 1\}^{n \times n}. $$

(6a)

To solve the optimization problem (6), we re-formulate it from several aspects. First, we denote the anomaly score $S_i(A)$ for node $v_i$ as a normalized distance to the regression line. To reduce the non-linearity and ease optimization, we omit the normalization term and use a proxy $\tilde{S}_i(A) = \ln(E_i) + 1$ to approximate $S_i(A)$. Consequently, we will use an objective function $\tilde{S}_T(A) = \ln(E_i) + 1$ acting as the surrogate of $S_T(A)$ in the optimization process. We emphasize that $\tilde{S}_T(A)$ is only used in the optimization process and we use the true anomaly scores $S_T(A)$ for evaluation. Second, OddBall uses OLS point estimation to learn the model parameters $\beta_0$ and $\beta_1$, which have closed-form solutions (Eqn. (2)). This allows us to directly substitute $\beta_0$ and $\beta_1$ with functions of $A$. At last, we can explicitly write the features $N_i$ and $E_i$ as $N_i = \sum_{j=1}^{n} A_{ij}$, $E_i = N_i + \frac{1}{2} A_i^2$. Finally, we can re-formulate the attack problem as:

$$A^* = \arg \min_A \tilde{S}_T(A)$$

$$= \arg \min_A \sum_{i \in T} (E_i - e^{\beta_0 N_i + \beta_1})^2, $$

s.t. $N_i = \sum_{j=1}^{n} A_{ij}, \quad E_i = N_i + \frac{1}{2} A_i^2;$

$$\frac{1}{2} \|A_0 - A\|_1 \leq B, \quad A \in \{0, 1\}^{n \times n}. $$

(7a)

Solving the above one-level discrete optimization problem leads to the optimal structural poisoning attacks.

### 4.2.2 Attacking GCN-based GAD Systems

We now formulate the structural poisoning attacks against GCN-based GAD Systems. One challenge is that these GAD systems have their unique characteristics, meaning that designing specific attacks for each system would be troublesome. In addition, GCN-based systems involve sophisticated training processes, imposing extra challenges to solving the attack optimization problem. To address these challenges, we propose to construct a simplified GCN model termed LGCN as a surrogate model, which represents the common graph convolutional process shared by all those GCN-based GAD systems. Thus, by attacking this surrogate LGCN model, we can generalize the attacks to all GCN-based GAD systems. In addition, a nice feature of LGCN is that we can use close-form (Ridge weighted least square estimation [25, 26]) functions to approximate its training process, which will significantly reduce the complexity of solving the attack optimization problem by transforming the complex bi-level optimization problem to one-level version.

Referring to [8], we construct the LGCN model by replacing the activation function (Like ReLU [27]) of the convolutional layer [4] with the linear activation function. In this paper, we consider a two-layered LGCN:

$$\hat{A} = \text{diag}(\sum_{i=1}^{n} A_i) - \frac{1}{2} (\hat{A} + 1) \text{diag}(\sum_{i=1}^{n} A_i) - \frac{1}{2},$$

$$Z = \text{sigmoid}(\hat{A} \hat{A} \hat{W}^1 \hat{W}^2) = \text{sigmoid}(\hat{A}^2 \hat{W}),$$

(8a)

(8b)

here $\hat{W}^1$ and $\hat{W}^2$ represent the weights for the first and second GCN layer. We use sigmoid instead of softmax for sake of transferring the nonconvex deep learning model to a convex logistic regression. The corresponding reweighting binary cross-entropy loss is defined as:

$$L_\text{BCE} = -\sum_{i=1}^{n} (y_i \log(Z_i) + (1 - y_i) \log(1 - Z_i)), $$

(9)

where $\omega$ is the ratio of positive samples number to negative samples number. However, the optimal $\hat{W}^*$ can only be approximated by vanilla gradient descent under this scenario. Crucially, we instead replace the cross-entropy loss
with mean square loss in order to reach $W^*$ without tedious training. As a result, we have new loss as:

$$\mathcal{L}_{\text{R-MSE}} = \sum_{i=1, y_i=1}^n (\omega(y^i - (\tilde{A}^2X)_i))^2 + \sum_{i=1, y_i=0}^n (y^i - (\tilde{A}^2X)_i)^2$$

$$= (Y - \tilde{A}^2X)^T D (Y - \tilde{A}^2X), \tag{10}$$

where

$$D = \begin{pmatrix}
\omega y^1 & 0 & \cdots & 0 \\
0 & \omega y^2 & \cdots & 0 \\
\vdots & \vdots & \ddots & \vdots \\
0 & 0 & \cdots & \omega y^n
\end{pmatrix}$$

is a diagonal matrix. Eqn. (10) is the loss function of weighted least square (WLS) [26] problem. The point estimate of WLS is

$$W^* = ((\tilde{A}^2X)^T D \tilde{A}^2X)^{-1} (\tilde{A}^2X)^T DY. \tag{11}$$

In consideration of the singularity matrix $(\tilde{A}^2X)^T D \tilde{A}^2X$ caused by $p > n$ (singular matrix does not have its inverse), we add Ridge penalty [25] on $\mathcal{L}_{\text{R-MSE}}$ to ameliorate the high dimensional problem and obtain:

$$\mathcal{L}_{\text{RR-MSE}} = (Y - \tilde{A}^2X)^T D (Y - \tilde{A}^2X) + \zeta W^T W, \tag{12}$$

the corresponding point estimate of $W^*$ is:

$$W^* = ((\tilde{A}^2X)^T D \tilde{A}^2X + \zeta I_{p \times p})^{-1} (\tilde{A}^2X)^T DY. \tag{13}$$

During the testing phase, we feed $W^*$ to LGCN and get the prediction score $\hat{Z} = \text{sigmoid}(\tilde{A}^2X W^*)$ for prediction.

Since the GCN-based GAD system is a supervised structural poisoning attacks, the attacker’s goal is to decrease the classification accuracy of the surrogate model in the previous context under the limited budgets. The reformulation of the objective is:

$$A^* = \arg \min_A -\mathcal{L}_{\text{R-BCE}}(A, X, W^*, Y);$$

s.t. $W^* = \arg \min_W \mathcal{L}_{\text{RR-MSE}}(A, X, W, Y), \tag{14}$$

$$\frac{1}{2} ||A_0 - A||_1 \leq B, \quad A \in \{0, 1\}^{n \times n}.$$

Here we emphasize that the attack loss $\mathcal{L}_{\text{R-BCE}}$ can be partitioned into two parts to incorporate the information of the training and testing data:

$$\mathcal{L}_{\text{R-BCE}}(Y) = h\mathcal{L}_{\text{R-BCE}}(Y^{\text{train}}) + (1-h)\mathcal{L}_{\text{R-BCE}}(Y^{\text{test}}), \tag{15}$$

where $Y^{\text{train}}$ is the training node labels, $Y^{\text{test}}$ is the predictions for the testing node labels based on the pre-trained LGCN. Referring to [9], we choose $h = 0.5$ during training phase. With the help of the close form of $W^*$, we can transform the bi-level optimization problem to the one-level case:

$$A^* = -\arg \min_A \mathcal{L}_{\text{R-BCE}}(A, X, W^*, Y);$$

s.t. $A = \text{diag}(\sum_{i=1}^n A_i) - \frac{1}{2} (A + I) \text{diag}(\sum_{i=1}^n A_i) - \frac{1}{2}$,

$$W^* = ((\tilde{A}^2X)^T D \tilde{A}^2X + \zeta I_{p \times p})^{-1} (\tilde{A}^2X)^T D Y^{\text{train}},$$

$$\frac{1}{2} ||A_0 - A||_1 \leq B, \quad A \in \{0, 1\}^{n \times n}. \tag{16}$$

Solving $A^*$ lead to an optimal solution to the above discrete optimization problem.

## 5 ATTACK METHODS

Now, the task of designing structural poisoning attacks amounts to solving the two optimization problems [7] and [16]. In this section, we introduce three methods, GradMaxSearch, ContinuousA, and BinarizedAttack. Specifically, the first two proposed methods GradMaxSearch and ContinuousA are adapted from typical approaches in the literature for solving similar problems. We further propose BinarizedAttack to address their limitations.

### 5.1 Conventional Methods

Solving the optimization problem [7] to obtain the optimal graph structure is hard in general, mainly due to the integer variables involved. Thus a common approach is to relax the integral constraints, transforming the optimization problem to its continuous counterpart, for which gradient-descent-based optimization techniques could be employed. Ideally, a continuous optimal solution $\hat{A}^*$ is obtained, which is then transformed to a discrete solution $A^*$. This approach faces two central challenges: i) how to use the gradient information for the guidance of searching for $\hat{A}^*$, and ii) how to discretize $\hat{A}^*$ to obtain $A^*$. Based on the previous works in the literature, we propose two methods.

#### 5.1.1 GradMaxSearch

Most of the previous works on structural attacks utilize a greedy strategy to solve the optimization problem in an iterative way. Specifically, the integer constraints on $A$ are relaxed and in each iteration, the gradients of the objective with respect to each entry of $A$ are calculated. Then, the entry with the largest gradient is picked for alternation (either deleting or adding an edge). Intuitively, a larger gradient indicates a bigger impact on the objective value. The iteration continues until budget constraint $B$ is reached. Attacking LGCN with GradMaxSearch is similar to attacking OddBall.

Regarding the implementation of GradMaxSearch, we note that when picking the entry associated with the largest gradient, one should pay attention to the signs of the gradients. For example, when $A_{ij} = 0$ we need to ensure that the corresponding gradient $\frac{\partial \mathcal{L}_{\text{R-BCE}}}{\partial A_{ij}} < 0$ (and vice versa) to make the operation (add or delete) valid. In addition, to avoid repeatedly adding and deleting the same edge, we maintain a pool to record the edges that have not been modified. Meanwhile, we also avoid the operations that would result in singleton nodes.

#### 5.1.2 ContinuousA

Softening the discrete objective is another concerns. An apparent bottleneck of GradMaxSearch is that the one-level discrete objective function is only optimized through $B$ steps, where $B$ is the attacker’s budget. An alternative way is thus to totally treat $\hat{A}$ as continuous variables $\hat{A} \in [0, 1]^{n \times n}$ and optimize the objective function until it converges.

In detail, by solving the optimization problem in the continuous domain using gradient-descent, we obtain the
sub-optimal continuous solution \( \hat{A}^* \). We then calculate the differences in absolute values between the original \( A \) and \( \hat{A}^* \), and pick those edges associated with the top-\( B \) absolute differences to modify.

### 5.2 BinarizedAttack

Both GradMaxSearch and ContinuousA have their own limitations. For GradMaxSearch, one major limitation is that the gradient only indicates a relatively small fractional update on the corresponding entry in \( A \); while a discrete value (\( \pm1 \)) is actually updated. This would not necessarily optimize the objective. Moreover, due to budget constraint, \( B \) is only optimized through \( B \) steps. ContinuousA treating \( A \) as continuous in the whole process of optimization, totally ignoring the effect of discrete updates on the objective function. Furthermore, without careful design, converting from the fractional optimal solution \( \hat{A}^* \) to \( A^* \) may lead to arbitrary bad performances.

We propose BinarizedAttack to mitigate these limitations. At a high level, BinarizedAttack is a gradient-descent-based approach that optimizes the objective in iterations. Each iteration consists of a forward pass, where the objective function is evaluated on some decision variables, and a backward pass, where the decision variables are updated based on calculated gradients. The core idea of BinarizedAttack lies in the design of two sets of decision variables as well as the way of utilizing gradient information. Specifically, we associate each entry \( A_{ij} \) with a discrete dummy (the use of dummy will be explained later) decision variable \( \hat{Z}_{ij} \in \{-1, +1\} \), where \( \hat{Z}_{ij} = 1 \) indicates that the corresponding entry \( A_{ij} \) will be modified and vice versa. For example, if \( A_{ij} = 1 \) and \( \hat{Z}_{ij} = -1 \), we will change \( A_{ij} \) to 0. Let \( \hat{A} \) and \( A \) be the original and modified adjacency matrix, respectively, which are connected through the decision variables \( Z \) by

\[
A = (\hat{A} - 0.5 \cdot 1^{n \times n}) \odot Z + 0.5 ,
\]  

(17)

where \( \odot \) denotes element-wise multiplication between two matrices.

We further associate each entry \( A_{ij} \) with a continuous soft decision variable \( Z \in [0, 1] \) to facilitate gradient computation. The two sets of decision variables \( \hat{Z} \) and \( Z \) are related by

\[
Z = -\text{binarized}(2 \cdot \hat{Z} - 1),
\]  

(18)

where we define the function binarized(\( x \)) as binarized(\( x \)) = +1 if \( x \geq 0 \) and binarized(\( x \)) = -1 otherwise. Since our objective function \( S_T(A) \) depends on \( A \), we can easily rewrite it as a function relying on the decision variables \( \hat{Z} \) and \( Z \) as \( S_T(Z, \hat{Z}) \).

We proceed to handle budget constraint \( \mathcal{C} \). Our goal is to transform this constraint as part of the objective function so that we can thoroughly optimize the objective beyond \( B \) steps. To this end, we impose a LASSO penalty \( \|Z\|_1 \) on the continuous soft decision variables \( Z \). Our choice of LASSO comes from the fact that LASSO can obtain sparser solutions compared with the L2 penalty \( \|Z\|_2 \). Based on Eqn. (18), we can observe that a larger \( \hat{Z}_{ij} \) indicates that it is more likely to modify the entry \( A_{ij} \) (i.e., \( Z_{ij} = -1 \)). As a result, in the optimization process, while the LASSO penalty term pushes the entries in \( \hat{Z} \) to zero, it is also restricting the modifications made to \( A \), achieving a similar effect of the budget constraint.

#### 5.2.1 Attacking OddBall

Now, we can reformulate the attack problem as an optimization problem with \( \hat{Z} \) and \( Z \) as decision variables:

\[
\hat{Z}^* = \arg \min_{\hat{Z}} \sum_{a=1}^{r} (E_a - e^\rho)^2 + \lambda \|Z\|_1 ;
\]  

(19a)

\[
s.t. \quad \rho = (1, \ln N)^T ([1, \ln N]^T [1, \ln N])^{-1} [1, \ln N]^T \ln E ;
\]  

(19b)

\[
A = (A_0 - 0.5 \cdot 1^{n \times n}) \odot Z + 0.5 ;
\]  

(19c)

\[
Z = -\text{binarized}(2 \cdot \hat{Z} - 1) .
\]  

(19d)

Note that we used a parameter \( \lambda \) to tune the relative importance of the adversarial objective and the penalty term.

Now, we can solve (19) through iteration. Specifically, in the forward pass, we will evaluate the objective by the discrete dummy variables \( Z \). Intuitively, this will more accurately measure the effect of discrete updates of the graph structure on the objective. In the backward pass, we can compute the gradients with respect to \( \hat{Z} \), and update \( Z \) from (19e). In this way, by observing \( Z \), we can obtain the entries in \( A \) that the attacker needs to modify. We note that the discrete variables \( Z \) are only used to evaluate the objective function for optimization; the final decisions are made from the soft variables \( Z \), thus the reason why \( Z \) are called dummy variables.

#### 5.2.2 Attacking LGCN

As for attacking LGCN, similarly we deploy the interaction between a discrete decision variable \( Z \in \{-1, +1\}^{n \times n} \) and continuous random variable \( \hat{Z} \in [0, 1]^{n \times n} \) by Eqn. (18). Then the objective function of BinarizedAttack is:

\[
\hat{Z}^* = \arg \min_{\hat{Z}} - \mathcal{L}_{R-BCE}(A, X, W^*, Y) + \lambda \|Z\|_1 ;
\]  

(20a)

\[
s.t. \quad \hat{A} = \text{diag}(\sum_{i=1}^{n} A_i) - \frac{1}{2} (A + 1) \text{diag}(\sum_{i=1}^{n} A_i) - \frac{1}{2} ,
\]  

(20b)

\[
W^* = ((\hat{A}^2 X)^T D \hat{A}^2 X + \xi I_{p \times p})^{-1} (\hat{A}^2 X)^T D Y^{train} ,
\]  

(20c)

\[
A = (A_0 - 0.5 \cdot 1^{n \times n}) \odot Z + 0.5 ;
\]  

(20d)

\[
Z = -\text{binarized}(2 \cdot \hat{Z} - 1) .
\]  

(20e)

The training procedure of the BinarizedAttack against LGCN is shown in Alg. [1]. We leave the model comparison between the three attack methods based on the surrogate model in the experiment part.

After the training phase of the structural attacks against the surrogate model, we ideally feed the poisoned graphs under different attack power into six popular GAD systems with the GCN as their backbone in a black-box manner: GCN-reweight [7], GAT-reweight [24], FdGars [15], GEM [16], Player2vec [17], GraphSMOTE [18]. We leave the model description and the black-box attack results in the experiment part.
Algorithm 1: BinarizedAttack for LGCN

Input: clean graph $A^0$, budget $B$, surrogate model LGCN, training nodal labels $Y^{\text{train}}$, $\Lambda = \{\lambda_k\}_{k=1}^K$, iteration number $T$, learning rate $\eta$.

Parameter: Perturbation $Z$.
1. Pre-train LGCN and get prediction $\hat{Y}^{\text{test}}$ based on the prediction score: $Z_{\text{test}} = \text{sigmoid}(A^0 \omega X W^*)$.
2. Let $t = 0$ and initialize $Z$.
3. For $k \leftarrow 1, 2, ..., K$ do
4. while $t \leq T$ do
5. Forward Pass:
6. Calculate $Z = -\text{binarized}(2 \cdot Z - 1)$.
7. Calculate $A = (A^0 - 0.5 \cdot 1_{n \times n}) \odot Z + 0.5$.
8. Calculate the symmetric normalized Laplacian $\tilde{A} = \text{diag}(\sum_{i=1}^{n} A_i)^{-\frac{1}{2}}(A + I)\text{diag}(\sum_{i=1}^{n} A_i)^{-\frac{1}{2}}$.\[10.\]
9. Obtain RWLS point estimate $W^* = (\tilde{A}^{-2}X)^T \tilde{D}^{-1}(\tilde{A}^{-2}X^T + \xi I_{p \times p})^{-1}(\tilde{A}^{-2}X^T)DY^{\text{train}}$.
10. Obtain goal function $L_{R-BCE} + \lambda_k ||Z||_1$.
11. Backward Pass:
12. $\forall i, j \in 1, 2, ..., n$, calculate the gradient of the goal function $L_{R-BCE}$ w.r.t $Z_{ij}$, i.e., $\frac{\partial L_{R-BCE}}{\partial Z_{ij}}$.
13. Projection Gradient Descent:
14. $Z \rightarrow \prod_{[0,1]} (Z - \eta \frac{\partial L_{R-BCE}}{\partial Z_{ij}})$.
15. end while
16. return $Z$
17. end for
18. for $b \leftarrow 1, 2, ..., B$ do
19. Pick out $Z = \min L_{R-BCE}$ satisfies $\sum Z = -b$.
20. Get poisoned graph $A^b = (A^0 - 0.5 \cdot 1_{n \times n}) \odot Z + 0.5$.
21. return $A^b$.
22. end for

6 Experiments
6.1 Datasets and Experiment Settings
6.1.1 Datasets

BA (Barabasi-Albert) [50] is a graph generative model which incorporate the idea of preferential attachment on the links probability. We set the number of edges attaching from a new node to existing nodes is 5. Blogcatalog [31] is a social network indicating follower/followee relationships among bloggers in a blog sharing website. The network has 88,800 nodes and 2.1M edges. Wikivote [32] contains all the Wikipedia voting data from the inception of Wikipedia till January 2008. Nodes in the network represent Wikipedia users and the edge represents that user $i$ voted on user $j$. The dataset contains around 7000 nodes and 0.1M edges.

Bitcoin-Alpha [33] is a who-trusts-whom social network of traders who trade Bitcoin on the Bitcoin-Alpha platform. It is a weighted signed network with weights ranging from +10 to −10. It has more than 3000 nodes and 24186 edges. We pre-process the data by removing all the negative edges and erasing the weights of all the remaining edges, resulting in an unsigned unweighted version of Bitcoin-Alpha. For Wikivote and Bitcoin-Alpha we randomly sample the connected sub-graph with around 1000 nodes from the whole graph.

Citeeseer [54], Cora [55], Cora-ML [56] are the citation networks which well capture the citation relations and co-authors relations. ca-GFQc [37] is a collaboration network from the e-print arXiv and covers scientific collaborations between authors papers submitted to General Relativity and Quantum Cosmology category. For all the real-world graph data we pick out the largest connected component to prevent the present of the isolated nodes. The statistics of the real datasets are summarized in Table 1. Here Citeeseer-Wo means we only consider the structural information of Citeeseer dataset.

6.1.2 Setting

For datasets in Tab. 1 we analyze the structural poisoning attacks against OddBall with the first six datasets. We determine our target set by sampling 10 target nodes from the top-50 nodes based on AScore (From now on we denote anomaly score as AScore for simplicity) rankings. For each experiment, we sample target nodes 5 times individually and report the mean values to measure the efficacy of the structural attack on OddBall. For structural attack (add/delete edges) on node anomaly detection, we aim to minimize the AScore sums for target set $V$ under different budget constraints. We determine the max budget $B$ for each case by the convergence of AScore for the three structural attacks. We stop attacking until the changes of AScore saturated.

We explore the structural poisoning attacks against the LGCN with the last three datasets in Tab. 1. We synthetically inject structural anomalies into these datasets and flag the perturbed nodes as anomalous. Referring to [38], we randomly choose some nodes in the clean graph and inject cliques to make them fully connected. We split the dataset into training and testing part, the ratio of training to testing is 9 : 1. We split the dataset 5 times and report the mean AUC scores for model comparison.

6.2 Attack Performance

6.2.1 Effectiveness of attack OddBall

Our main focus is to investigate whether the proposed attack methods can effectively decrease AScores of the target nodes. We use the Decreasing Percentage of AScore denoted as $\tau_{\text{as}}$, as the evaluation metric. Specifically, let $S_T^0$ and $S_T^B$ be the sum of AScores of the target nodes before attack and after an attack with a budget $B$, respectively. Then, $\tau_{\text{as}}$ is defined as $\tau_{\text{as}} = (S_T^0 - S_T^B)/S_T^0$.

Fig. 1 presents the $\tau_{\text{as}}$ of the three attack methods, BinarizedAttack, GradMaxSearch, and ContinuousA, with varying attack power. In particular, the attack power is measured as a percentage $B/|E|$, where $|E|$ is the number of edges in the clean graph. We note that in all the cases, the attacker has modified very limited edges in the graph: less than 2% when $|V| = 10$.

We can observe from Fig. 4 that both BinarizedAttack and GradMaxSearch can significantly (up to 90%) decrease AScores with very limited power while ContinuousA is not effective in several cases. This demonstrated the unpredictable feature of ContinuousA when converting continuous solutions to discrete ones. Our main method BinarizedAttack consistently achieves the best performance in all cases. We note that the margin between BinarizedAttack and GradMaxSearch is significant (with a > 10% performance improvement) when the attack power is high (although the two lines look close in the figures). For example, in Fig. 4e when the attack power is 0.5%, BinarizedAttack outperforms GradMaxSearch by 41.01%. One intriguing observation is that the gap between BinarizedAttack and GradMaxSearch becomes larger when we increase the attacker’s budget. The reason is that GradMaxSearch is a greedy strategy in nature and should perform well when modifying a few edges; meanwhile, it is also myopic when the budget is large.

The computational bottleneck of BinarizedAttack lies in computing the egonet edge features \(E_i\) for all nodes, which involves calculating \(A^3\). We use two techniques to allow BinarizedAttack to scale to large graphs. First, we use the sparse matrix representation of the adjacent matrix \(A\) and implement all the the computations based on sparse matrix techniques. Empirically, we observe that, on the largest dataset ca-GrQc, using sparse matrix can introduce an around \(\times 10\) speed increase. Second, we observe through our experiments that BinarizedAttack will almost only modify the edges directly connected to the target nodes. For example, the percentage of direct edges are 94.7% for Bitcoin-Alpa. As a result, we can design a variant of BinarizedAttack, termed BinarizedAttack-Direct, where the attacker is retreated to altering the direct connections to the target nodes. This will decrease the number of parameters involved in optimization; however, the cost is that the performance of attack might be sacrificed. We implemented BinarizedAttack-Direct on the largest dataset ca-GrQc. The results shows that BinarizedAttack-Direct will increase the speed by around 2 times with a reasonable performance sacrifice (Fig. 4).

We further show in Fig. 5 how BinarizedAttack will actually modify the structure of a real-world graph (Wikivote as the example). We demonstrated three cases, where the attacker deletes edges only, adds edges only, and deletes and adds edges simultaneously. It shows that BinarizedAttack will indeed break the anomalous structural patterns (i.e., near-star and near-clique) in the graph.

6.2.2 Effectiveness of attack LGCN

For attacking supervised graph anomaly detection, we focus on analyzing the attack efficacy of three attack methods.
by measuring the changes in the overall AUC scores after attack. Fig. 6 presents the mean testing AUC scores of the proposed three attack methods with different attacking powers. Since it is a global attack, we may increase the degree attack power to up to around 30% to highlight the attacking performance on the supervised graph anomaly detection.

We observe that similar to attacking OddBall, our main method BinarizedAttack consistently outperforms the other two baseline methods in all the three real-world datasets. Especially, when the attacking power increase to up to 30% for Citeseer, BinarizedAttack can effectively misguide the LGCN for anomaly node detection (AUC = 0.5 means the classification is totally a random guess). At the same time, the AUC margin between BinarizedAttack and GradMaxSearch increase to up to around 0.15 for Citeseer and around 0.08 for Cora.

6.2.3 Attacks against GCN-Based GAD Systems

In this section, we explore the black box attacks of the BinarizedAttack against LGCN on other GCN-based GAD models: GCN-reweight, GAT-reweight, FdGars, GEM, Player2vec and GraphSMOTE on Cora and Citeseer dataset as exemplars. We measure the attack efficacy of black-box attacks with the mean AUC scores on the testing data. The results are shown in Tab. 2. BR is the modified edges percentage range. We can observe that BinarizedAttack against LGCN has a significant effect on the global accuracy of those six GCN-based GAD systems especially for FdGars. That is, when the attacking power increases to more than 20%, the mean AUC scores for Cora and Citeseer decrease to 0.48 and 0.52, resulting in an approximately useless anomaly detector. On the other hand, the biggest gap for mean AUC scores before and after an attack is the black box attack against GEM on Cora dataset, which is up to around 32% (decreased from 0.72 to 0.49). In general, the results in Tab. 2 shows that BinarizedAttack against LGCN as a surrogate model can effectively influence the GCN backbones of the other GAD systems, resulting in respectable attack efficacy in black-box attack manner.

6.3 Side Effects of Attack OddBall

BinarizedAttack is a structural targeted attack that aims to mislead the predictions of a small set of target nodes in poisoning manner. A desirable character is that the attack would not significantly change the data distribution to the extent that the poisoned data would look abnormal for a smart defender. In other words, an attacker wants to make the attack unnoticeable. In this paper we assume the detector is specially caring about the ego-features distribution.

In our context, BinarizedAttack modifies the features \((N_i, E_i)\) of the ego-net centered at node \(i\). By design, BinarizedAttack will significantly modify the features of targeted nodes; however, an inevitable side effect for the structural attack against OddBall is that BinarizedAttack would also change the features of the rest of the nodes. In the worst case, the shift of the feature distributions caused by an attack is so large that the attacked graph would appear abnormal and be easily detected by the defender. Thus, ideally, we would expect the side effect of BinarizedAttack is reasonably small to achieve an unnoticeable attack.

We thus experiment to investigate the shift of distribution of the ego-features \((N, E)\) before and after BinarizedAttack. Specifically, we deploy the permutation test\(^{39}\), which is a general non-parametric test to check whether two different independent data groups follow the same distribution. However, it will be NP-hard for the permutation test if we consider all kinds of perturbations in the concatenation of two data groups. We thus refer to the Monte Carlo way to approximate the \(p\)-value with sufficient experiment times, which is computed as:

\[
p(t \geq t_0) = \frac{1}{M} \sum_{j=1}^{M} I(t_j \geq t_0),
\]

where \(t_0\) is the observed value of test statistic and \(t\) is the statistic calculated from the re-samples, i.e., \(t(x_1', x_2', ..., x_n', y_1', y_2', ..., y_n') = |x' - y'|\), \(M\) is the Monte Carlo sampling times (in the experiment we set \(M = 100000\)). \(x\) and \(y\) can be either \(N^\text{clean}\) and \(N^\text{poisoned}\) or \(E^\text{clean}\) and \(E^\text{poisoned}\). \(x'\) and \(y'\) are re-samples of \(\text{Concat} [N^\text{clean}, N^\text{poisoned}]\) or \(\text{Concat} [E^\text{clean}, E^\text{poisoned}]\).

We report the \(p\)-value of ego-features \(N\) and \(E\) on two real datasets: Bitcoin-Alpah and Wikivote. The results are shown in Tab. 3, where we consider ego-features of the poisoned graph with maximum perturbations and \(|V| = 30\).

From Tab. 3, we notice that under 99% significant level we cannot reject the null hypothesis that \(N^\text{clean}\) and \(N^\text{poisoned}\) follows the same distribution, that is, we can draw the conclusion that BinarizedAttack does not manipulate the distribution of \(N\). For ego-feature \(E\), in most cases, we cannot reject the null hypothesis. However, in experiment 5 for Wikivote the \(p\)-value is less than 1%, so we reject the null hypothesis, that is, in Wikivote experiment 5 BinarizedAttack manipulate the distribution of \(E\) under...

Hence the introduction of RWLS makes a great contribution to the attack model.

6.4 Ablation Study on WLS

In this section, we start to discuss the contribution of the weighted least square estimation (WLS) in the attack model. If we set the diagonal matrix \( D = \text{Diag}(1, \ldots, 1)_{n \times 1} \), the point estimate of RWLS in Eqn. (13) changes to Ridge regression (25):

\[
\tilde{A} = \text{Diag}(\sum A_i)^{-\frac{1}{2}} (A + I) \text{Diag}(\sum A_i)^{-\frac{1}{2}},
\]

(22a)

\[
W^* = ((\tilde{A}^2 X)^T \tilde{A}^2 X + \xi I_{p \times p})^{-\frac{1}{2}} (\tilde{A}^2 X)^T Y.
\]

(22b)

We compare the decreasing percentage of mean AUC scores for RWLS and Ridge regression on Cora dataset as exemplar. Fig. 7 illustrates that by using RWLS as the point estimate for LGCN's weights, the attacking performance is significantly higher than Ridge regression (the decreasing percentage of mean AUC scores for RWLS is much larger than Ridge). This phenomenon is attributed to the fact that WLS incorporate the imbalanced sample numbers and pay more attention to the minority class during the training phase, leading to more suitable close form solutions of \( W^* \).

6.5 Sensitivity Analysis on \( \xi \)

Another important issue is the choice of the penalty parameter \( \xi \) for Ridge regression. According to Tab. 2, the dimension of the attributes for real-world graphs are usually more than one thousand, thus leading to a high-dimensional problem in the regression. The introduction of \( L2 \) penalty here can not only prevent the inexistence of the inverse of singularity matrix in the point estimate, but also highlight the important part of the nodal attributes to prevent over-fitting.

![Fig. 8: (a) RWLS vs Ridge; (b) is the sensitivity analysis on \( \xi \).](image)

7 CONCLUSION

In this paper, we initiate the study to investigate the vulnerability of graph-based anomaly detection under structural poisoning attacks. Specially, we target on OddBall as feature extraction based anomaly detector and LGCN as the surrogate model of the GCN-based anomaly detector, we further mathematically formulate it as a discrete one-level optimization problem by incorporating specially designed regression techniques (OLS estimation for OddBall and RWLS estimation for LGCN). We then propose a novel training procedure BinarizedAttack which effectively damages the target GAD systems, significantly outperforming existing...
methods. Moreover, we explore the black-box attacks of the typical six GCN-based GAD systems (GCN-reweight, GAT-reweight, FdGars, GEM, Player2vec and GraphSMOTE) and prove that by universally attacking LGCN can effectively transfer attack other GCN-based GAD systems in black-box manner. In the future work, it is interesting to explore the possible countermeasure against such poisoning attacks on graph data to enhance the robustness of the existed graph anomaly detectors.
