A simple normalization technique using window statistics to improve the out-of-distribution generalization on medical images

Chengfeng Zhou, Songchang Chen, Chenming Xu, Jun Wang, Feng Liu, Chun Zhang, Juan Ye, Hefeng Huang, and Dahong Qian, Senior Member, IEEE

Abstract—Since data scarcity and data heterogeneity are prevailing for medical images, well-trained Convolutional Neural Networks (CNNs) using previous normalization methods may perform poorly when deployed to a new site. However, a reliable model for real-world clinical applications should be able to generalize well both on in-distribution (IND) and out-of-distribution (OOD) data (e.g., the new site data). In this study, we present a novel normalization technique called window normalization (WIN) to improve the model generalization on heterogeneous medical images, which is a simple yet effective alternative to existing normalization methods. Specifically, WIN perturbs the normalizing statistics with the local statistics computed on the window of features. This feature-level augmentation technique regularizes the models well and improves their OOD generalization significantly. Taking its advantage, we propose a novel self-distillation method called WIN-WIN for classification tasks. WIN-WIN is easily implemented with twice forward passes and a consistency constraint, which can be a simple extension for existing methods. Extensive experimental results on various tasks (6 tasks) and datasets (24 datasets) demonstrate the generality and effectiveness of our methods.

Index Terms—Normalization, out-of-distribution generalization, multi-center data.

I. INTRODUCTION

DESPITE the tremendous success of CNNs in medical image analysis, they are mainly built upon the “i.i.d. assumption”, which states that training data and test data are independent and identically distributed. The assumption barely holds in real-world applications due to the nature of medical images, rendering the sharp drop of well-trained models on unseen data with distribution shifts [1]–[3]. Since the expensive costs for data acquisition and data annotation lead to data scarcity, the data used for model training can only capture a small population of real data distribution (see Fig. 1). Meanwhile, the data heterogeneity caused by inconsistent standards (e.g., various operating procedures and imaging equipment) worsens the distribution shifts in medical images. A slight difference in appearance results in significant model performance dips [2]. Therefore, OOD generalization on heterogeneous data is a crucial challenge for real-world clinical applications [4], [5].

The most straightforward solution is to acquire sufficient data from various sites and train a robust model. However, it would be high-cost and even impossible in real-world applications. In practice, another economic and popular solution is data augmentation. Data augmentation enhances the breadth of seen data with predefined class-preserving options, such as mixing multiple augmented images [6] and mixing an augmented image with dreamlike images [7]. With the help of the augmented samples simulating the unseen images, CNNs improve their generalization to OOD data. Although the data
augmentation methods no longer require significant manual designation efforts [8], [9], their performance is less appealing for improving the OOD generalization on medical images because they are mainly developed for the natural images with large domain gaps [10]–[12]. Besides, they may increase computing overhead and impede model convergence.

Normalization layers are essential components of modern CNNs. Traditional normalization techniques are generally and simplistically built upon the “i.i.d. assumption”. For instance, Batch Normalization (BN) [13] constrains intermediate features within the normalized distribution with mini-batch statistical information to stabilize and accelerate the training. It has a fundamental flaw, train-test statistics inconsistency, which worsens under distribution shifts. Instance normalization (IN) [14] overcomes this limitation through computing the normalization statistics consistently. During the training and testing, IN normalizes features with statistics of the spatial dimension. This procedure effectively reduces the data distribution (i.e., by eliminating the style discrepancy) and improves the OOD generalization [15]. But its improvement for OOD generalization is still inadequate. On this basis, subsequent studies directly combine it with other mechanisms to address the OOD generalization problem, but they are complicated and inefficient for medical images [15]–[20]. For instance, Jin et al. [17] designed a normalization technique that consists of three components: Style Normalization and Restitution Module, Dual Causality loss, and Dual Restitution Loss.

In this work, we implement the feature-level data augmentation by a simple yet effective normalization technique called Window Normalization (WIN) to improve the OOD generalization on heterogeneous medical images. WIN exploits the mean and variance of a stochastic window to perturb the normalization statistics with a mixup operation, which is extremely easy to use and remarkably effective. With the benefits of WIN, we introduce a novel self-distillation scheme WIN-WIN which forward passes the input in different model modes twice and compels the consistency between the outputs. WIN-WIN can be implemented with few codes and further improve the OOD generalization in classification tasks. We demonstrate that our methods can generally boost the OOD generalization of various tasks (such as glaucoma detection, breast cancer detection, chromosome classification, optic disc and cup segmentation, etc.), spanning 24 datasets, with free parameters and a negligible effect for IN data. Our main contributions are summarized as follows:

- **WIN** for improving OOD generalization on heterogeneous data. **WIN** is a good alternative for existing normalization methods, with free parameters and a negligible effect for IN data.
- **WIN-WIN** to fully exploit the **WIN** in classification tasks, which is easy to implement and significantly effective.
- We demonstrate through extensive experiments that our methods can significantly and generally boost the OOD generalization across various tasks. The code of our method is publicly available at [https://github.com/joelchief/windowNormalization](https://github.com/joelchief/windowNormalization).

### II. RELATED WORK

#### A. Data Augmentation

Data augmentation is an important tool in training deep models, which effectively increases the data amount and enriches the data diversity through random operations such as translation, flipping, and cropping [21]. Intuitively, simulated and augmented inputs or outputs could aid a model in learning the invariances among the data domains and improve its generalization to novel domains. Popular data augmentation techniques are conducted at either image-level or feature-level. Image-level augmentation usually needs manual designation, which is challenging due to the difficulty of simulating the data from unforeseen target domains. To this end, several methods automatically searched for the augmentation policies in their predefined search space [8], [9]. However, their performance on OOD data is doubtful as the augmentation policies were usually tuned to optimize performance on a particular domain.

However, the aforementioned methods inevitably introduce computational overhead. Our method implements the feature-level data augmentation by the essential normalization layers in CNNs and outperforms many prior data augmentation techniques for improving OOD generalization.

#### B. Normalization

Normalization layer is an essential module in deep models. Extensive normalization techniques have been proposed for various domains such as natural language processing, computer vision, and machine learning. A milestone study is Batch Normalization (BN) [13], which has verified its generality on a wide variety of tasks. Although BN has been empirically proven to accelerate the model convergence and combat overfitting, it exhibits several shortcomings because it computes the statistic along the batch dimension by default [24], [25]. For example, the instance-specific information is lacking. To this end, Li et al. [26] re-calibrated features via an attention mechanism and Gao et al. [27] added a feature calibration scheme into BN to incorporate this information. Instance Normalization (IN) [14] is another milestone study that normalizes features with statistics of the spatial dimension. It has been extensively applied in the field of image style transfer as it could eliminate instance-specific style discrepancy (namely, standardizing features with the mean and the variance of IN) [28]. However, IN eliminated the style information and resulted in inferior performance on in-distribution samples [15],
Following the BN and IN, Group Normalization (GN) [24] exploited the statistics of grouped channel dimensions to train the model with small batches. On the contrary, there are several normalization techniques that utilized statistics of partial regions [29], [30] instead of all pixels within a dimension (e.g., Batch Normalization, Instance Normalization, Layer Normalization [31], and Group Normalization). Ortiz et al. [29] proposed the local context normalization (LCN) in which each feature is normalized based on a window around it and the filters in its group. It has demonstrated its effectiveness in dense prediction tasks, including object detection, semantic segmentation, and instance segmentation applications.

Since it has been a subtle choice about which normalization techniques can be applied in a particular scenario, many studies have explored the combination of multiple normalizations. Batch-Instance Normalization (BIN) [19] adaptively balanced the BN output and the IN output with a learnable gate parameter. This gating mechanism also appeared in the Switchable Normalization (SN) series [18], [20] which combined three types of statistics estimated channel-wise [14], layer-wise [31], and minibatch-wise [13]. Besides, Qiao et al. [32] introduced another combination that stacked the BN with the GN rather than conducting a weighted summation operation. These multi-normalization combination methods enable better adaptability and easy usage for various deep networks and tasks. However, they usually bring the extra computational cost.

Above normalization techniques are proposed under the assumption that training and test data follow the same distribution. Meanwhile, numerous normalization studies are proposed to address the distribution shifts between training and test distribution in real-world applications. For example, Mode Normalization [33] assigned the samples to different modes and normalized them with their corresponding statistics. Li et al. [5] used local batch normalization to address non-iid training data. Tang et al. [16] enlarged the training distribution with CrossNorm and bridged the gaps between training and test distribution with SelfNorm. Since the IN can effectively alleviate the style discrepancy among domains/instances, Pan et al. [15] mixed IN and BN in the same layer to narrow the distribution gaps and Jin et al. [17] proposed a style normalization and restitution module to eliminate the style variation and preserve the discrimination capability. Compared to these methods, WIN simply yet effectively addresses the OOD generalization problem. It has zero parameters to tune and no need for cautious choices of plug-in manner. As a variant of IN, it can be directly employed as the normalization layers and bring free benefits for OOD generalization.

### III. METHODS

#### A. Background

Normalization methods usually consist of feature standardization and affine transformation operations. Given the input feature \( f \in \mathbb{R}^{N \times C \times H \times W} \) in 2D CNNs, where \( N, C, H, \) and \( W \) are batch size, channel number, height, and width of the input feature, respectively. The feature standardization and affine transformation can be formulated as follows:

\[
\text{Standardization} : \tilde{f} = \frac{f - \mu}{\sqrt{\sigma^2 + \epsilon}},
\]

\[
\text{Affine} : \bar{f} = \gamma \odot \tilde{f} + \beta.
\]

\( \mu \) and \( \sigma^2 \) denote the mean and variance, respectively. \( \gamma \) and \( \beta \) are learnable affine parameters. \( \epsilon \) is used to prevent zero variance.

In BN, the mean and variance during training are defined as follows:

\[
\mu_{BN}^c = \frac{1}{NHW} \sum_{n=1}^{N} \sum_{h=1}^{H} \sum_{w=1}^{W} f_{n,c,h,w},
\]

\[
\sigma_{BN}^2 = \frac{1}{NHW} \sum_{n=1}^{N} \sum_{h=1}^{H} \sum_{w=1}^{W} (f_{n,c,h,w} - \mu_{BN})^2.
\]

\( \mu_{BN}, \sigma_{BN}^2 \in \mathbb{R}^C \) are computed within each channel of \( f \) (see Fig. 2 (a)). During the evaluation, the mean and variance are computed by aggregating the values of the pixels in blue. And, these pixels share the same normalizing statistics. (d) The schematic illustration of WIN-WIN (right) and WIN (left). WIN is adopted as the normalization layer in CNNs. It uses mixing statistics during the training and global statistics during the evaluation. \( x \) denotes the inputs. \( \hat{y} \) and \( \bar{y} \) are the prediction logits in training mode and evaluation mode, respectively. WIN-WIN passes the input \( x \) twice and compels the consistency between outputs \( \hat{y} \) and \( \bar{y} \).

\[
\text{WIN-WIN} : \frac{y}{\sqrt{\epsilon^2 + \sigma^2}} \Rightarrow \text{BN} \Rightarrow \frac{y}{\sqrt{\epsilon^2 + \sigma^2}} \Rightarrow \text{WIN}.
\]
Algorithm 1: Window sampling

Data: Features $f \in \mathbb{R}^{N \times C \times H \times W}$, Threshold $\tau$, Window ratio $\tau'$, Window width $\bar{W}$, Window height $\bar{H}$, Window center $(x, y)$;
Result: Top-left of window $(\tilde{x}, \tilde{y})$, Bottom-right of window $(\bar{x}, \bar{y})$;
1 repeat
// get a squared window
2 Uniformly sample a window ratio $\tau' \sim U(0.0, 1.0)$;
3 $\bar{W} \leftarrow W \ast \text{sqrt}(\tau')$;
4 $\bar{H} \leftarrow H \ast \text{sqrt}(\tau')$;
5 Uniformly sample a window center $(x, y)$;
// place the window
6 $\tilde{x} \leftarrow \text{int}(\max(x - W // 2, 0), W)$;
7 $\tilde{y} \leftarrow \text{int}(\max(y - \bar{H} // 2, 0), \bar{H})$;
8 $\bar{x} \leftarrow \text{int}(\max(x + W // 2, 0), W)$;
9 $\bar{y} \leftarrow \text{int}(\max(y + \bar{H} // 2, 0), H)$;
10 until $(\tilde{x} - \bar{x}) \times (\tilde{y} - \bar{y}) \geq \tau \times \bar{H} \times \bar{W}$;

$IN$ defines the mean and variance as follows:

$$
\mu_{IN}^{n,c} = \frac{1}{|WIN|} \sum_{n=1}^{N} \sum_{c=1}^{C} \sum_{w=1}^{W} f_{n,c,h,w},
$$

$$
\sigma_{IN}^{2,n,c} = \frac{1}{|WIN|} \sum_{n=1}^{N} \sum_{c=1}^{C} \sum_{w=1}^{W} (f_{n,c,h,w} - \mu_{IN})^{2}.
$$

$\mu_{IN}, \sigma_{IN}^{2} \in \mathbb{R}^{N \times C}$ are computed across spatial dimensions independently for each channel and each instance (see Fig. 2(b)). In addition, $\mu_{IN}$ and $\sigma_{IN}^{2}$ encode the instance-specific style information. Thus, standardizing the feature using $\mu_{IN}$ and $\sigma_{IN}^{2}$ is a kind of style normalization. Style normalization will eliminate the feature variance caused by appearance, which benefits the OOD generalization. However, it inevitably removes some discriminative information and degrades the IND generalization [15]. In the $IN$, the calculation of mean and variance is consistent during the training and evaluation, and the affine transformation which adopts $\gamma_{IN} \in \mathbb{R}^{N \times C}$ and $\beta_{IN} \in \mathbb{R}^{N \times C}$ is usually deactivated in practice.

B. Window Normalization

Our main inspiration is the observation of Ghost Batch Normalization (GBN) [34] which improves the model generalization with the mean and variance calculated on small parts of the input batch. Intuitively, GBN is equivalent to adding different noises to different slices of a batch, which is a kind of feature-level data augmentation. On the other hand, $IN$ demonstrated its superiority for OOD generalization on medical images [35]. Therefore, we introduce the $WIN$ which injects noises into each instance instead of slices of batch.

Specifically, the perturbation (i.e., noise injection) for each instance is conducted with the feature standardization operation. We standardize the feature $f$ with approximations of global statistics (i.e., $\mu_{IN}$ and $\sigma_{IN}^{2}$) (see Eq. 1). As shown in Fig. 2 (c), the mean and variance for each channel and instance are calculated within a random window. Formally, given a window that is specified by the top-left coordinate $(\tilde{x}, \tilde{y})$ and bottom-right coordinate $(\bar{x}, \bar{y})$, the mean and variance, $\mu_{WIN}, \sigma_{WIN}^{2} \in \mathbb{R}^{N \times C}$ are computed as:

$$
\mu_{WIN}^{n,c} = \frac{1}{\bar{H} \bar{W}} \sum_{h=\tilde{x}}^{\bar{x}} \sum_{w=\tilde{y}}^{\bar{y}} f_{n,c,h,w},
$$

$$
\sigma_{WIN}^{2,n,c} = \frac{1}{\bar{H} \bar{W}} \sum_{h=\tilde{x}}^{\bar{x}} \sum_{w=\tilde{y}}^{\bar{y}} (f_{n,c,h,w} - \mu_{WIN})^{2},
$$

where $\bar{H}$ and $\bar{W}$ are the height and width of a window. Algorithm 1 demonstrates the Window sampling strategy: we repeat generating a window denoted as $\{x, y, \bar{H}, \bar{W}\}$ and placing this window on the feature until the size of the random window exceeds $\tau \times \bar{H} \times \bar{W}$. $\tau$ is a threshold for the ratio of window size. LCN [29] also uses the statistics of windows, but they normalize each feature based on the statistics of its local neighborhoods and corresponding feature group. Besides, their prime use is in dense prediction tasks such as object detection, semantic segmentation, and instance segmentation.

Considering such perturbation is marginal for the images with consistent background (e.g., chromosome images), we propose another strategy called $Block$ which computes the $\mu_{WIN}$ and $\sigma_{WIN}^{2}$ within multiple small windows. Firstly, we divide the input feature $f$ into $B$ non-overlapping blocks. Each block corresponds to a particular patch on the input image regardless of the scale of feature. At a certain scale $s$, the $i$-th block is denoted as $\{\hat{x}_{i}, \hat{y}_{i}, \tilde{x}_{i}, \tilde{y}_{i}\}$. For example, the resolution of input images is $224 \times 224$ and the patch size is $32 \times 32$, so they will be divided into 49 blocks regardless of the feature scales. Then, we sample $\tau B$ random blocks without replacement, following a uniform distribution. The mean and variance $\mu_{WIN}, \sigma_{WIN}^{2}$ at the scale $s$ are computed as:

$$
\mu_{WIN}^{n,c} = \frac{1}{(\tau B)(\bar{H} \bar{W})} \sum_{i} \sum_{h=\tilde{x}}^{\bar{x}} \sum_{w=\tilde{y}}^{\bar{y}} f_{n,c,h,w},
$$

$$
\sigma_{WIN}^{2,n,c} = \frac{1}{(\tau B)(\bar{H} \bar{W})} \sum_{i} \sum_{h=\tilde{x}}^{\bar{x}} \sum_{w=\tilde{y}}^{\bar{y}} (f_{n,c,h,w} - \mu_{WIN})^{2},
$$

where $i$ is the index of random blocks and $\hat{H}$ and $\hat{W}$ are the original height and width of the patches. This strategy avoids the zero variance (e.g., a window on the consistent background) effectively.

In order to diversify the perturbations and smooth the model response, $WIN$ mixes the local statistics and the global statistics. The mixing statistics can be formulated as follows:

$$
\mu = \lambda \mu_{WIN} + (1 - \lambda) \mu_{IN},
$$

$$
\sigma^{2} = \lambda \sigma_{WIN}^{2} + (1 - \lambda) \sigma_{IN}^{2},
$$

where $\lambda \in \mathbb{R}^{N \times C}$ is a random instance-specific weight sampled from a beta distribution $Beta(\alpha, \alpha)$.

To keep the evaluation deterministic, we adopt $\mu = \mu_{IN}$ and $\sigma^{2} = \sigma_{IN}^{2}$ during evaluation as the mixing statistics are approximations of global statistics (see Fig. 2). The mixing statistics are equivalent to global statistics when $\tau = 1.0$ or $\lambda = 1.0$.
C. Training and evaluation discrepancy

Normalizing the features with WIN can regularize the CNNs training effectively and improve the OOD generalization significantly. However, the evaluation statistics cannot be strictly aligned to training statistics and the model parameters are trained to fit features normalized by \( \mu_{WIN}, \sigma_{WIN} \), which degrades the model generalization. On the other hand, normalizing the feature with mixing statistics (i.e., training mode) or global statistics (i.e., evaluation mode) can produce two correlated views of the same sample. Minimizing the discrepancy between training and evaluation is a natural self-learning task to incorporate the invariance among different views \([36], [37]\).

To these ends, we introduce the WIN–WIN for classification tasks, which needs twice forward passes. As shown in Fig. 2(d), given the input \( x \) with a ground-truth label \( y \), the first pass uses mixing statistics to normalize the features and outputs a logits \( \hat{y} \), while the second pass uses global statistics to normalize the features and outputs a logits \( \bar{y} \). WIN–WIN will compel the model to minimize the Jensen–Shannon divergence between \( \hat{y} \) and \( \bar{y} \) and the cross-entropy between \( \hat{y} \) and \( \bar{y} \) and \( y \). The Jensen–Shannon divergence loss can be written as:

\[
L_{JSD} = \frac{1}{2} [D_{KL} (softmax(\hat{y}) || softmax(y)) + D_{KL} (softmax(\bar{y}) || softmax(y))]
\]

where the logits are converted to a probability vector via softmax function. Meanwhile, the cross-entropy loss can be written as:

\[
L_{CE} = \frac{1}{2} (H(softmax(\hat{y}), y) + H(softmax(\bar{y}), y)).
\]

Finally, the total loss for classification tasks can be written as:

\[
L_{Total} = L_{CE} + \delta L_{JSD}
\]

where \( \delta \) is used to balancing \( L_{CE} \) and \( L_{JSD} \).

IV. EXPERIMENTS

A. Datasets and Evaluation Metrics

To demonstrate the generality of our methods, the experiments covered a wide range of tasks: binary classification, multiclass classification, and image segmentation. And, the datasets range from common OOD generalization benchmarks to real-world applications. A noticeable domain gap is existing in the image appearance and image quality (see Fig. 3).

Binary Classification. Following \([35]\), we set up a benchmark using seven glaucoma detection datasets from seven sites collected with various scanners, including five public datasets (i.e., LAG, REFUGE, RIMONE-r2, ODIR, and ORIGA\textsuperscript{light}) and two private datasets (i.e., BY and ZR). BY and ZR are collected from Peking University Third Hospital and the Second Affiliated Hospital of Zhejiang University, respectively. Furthermore, the experiments were also conducted on an OOD generalization benchmark Camelyon17. Camelyon17 is a breast cancer detection benchmark of WILDS \([2]\), which includes five data sources. All images in Camelyon17 were resized from \( 96 \times 96 \) to \( 256 \times 256 \) to facilitate the window sampling. Fig. 3 (a) and (b) show two benchmarks’ example cases and sample numbers. Here, the evaluation metric we applied was the mean clean area under the curve (\( m-cAUC \)) following \([35]\). Each dataset was divided into 80% and 20% for training and validation, while other datasets were held out for testing. Before aggregating, each test dataset’s result (i.e., the area under the curve) will be recalibrated by its inherent difficulties. A slight difference to \([35]\) is that we only run it once, taking into account multiple test datasets and time-saving. Higher \( m-cAUC \) means better OOD generalization.

Multiclass Classification. As shown in Fig. 3 (c), we collected chromosome images from two hospitals using different microscopes to cross-evaluate the OOD generalization performance in chromosome classification, including 7931 samples from The Obstetrics Gynecology Hospital of Fudan University (RHH) and 51151 samples from The International Peace Maternity Child Health Hospital of China welfare institute (IPMCH). The dataset from one hospital was divided into a training set and a validation set according to the 80% : 20% proportion and another hospital data was used for testing. The result was reported in Top-1 accuracy (Acc.). Besides, we also conducted experiments on two robustness benchmarks CIFAR-10-C and CIFAR-100-C \([38]\) and a commonly used domain generalization (DG) benchmark Digit-DG \([11]\). CIFAR-10-C and CIFAR-100-C consist of 75 corrupted versions of the original test set. The metric for them is the mean corruption error (\( mCE \)) across all 15 corruptions and 5 severities for each corruption. Lower is better. Digit-DG consists of four handwritten digit recognition datasets (MNIST, MNIST-M, SVHN, and SYN) with distribution shifts for font style, stroke color, and background. Following prior DG works \([10]\), we applied the leave-one-domain-out protocol for Digit-DG and reported the Top-1 accuracy on each target dataset. Chromosome images, CIFAR-10-C, and CIFAR-100-C were resized to \( 256 \times 256 \) and the images of Digit-DG were resized to \( 224 \times 224 \).

Image Segmentation. We employed the retinal fundus images in \([4]\) for optic cup and disc (OC/OD) segmentation. As shown in Fig. 3 (c), they are collected from 4 sites using different scanners \([4]\), and each image was center-cropped and resized to \( 384 \times 384 \) as network inputs. We randomly divided the images on each site into training and test sets following the proportion of 80% : 20%. In our experiments, the training sets of three sites (e.g., Site A, B, and C) were used for training, and the test set of remaining site (e.g., Site D) was used for testing. It is a common setting of DG. The segmentation result was reported in the Dice coefficient (\( Dice \)). Higher is better.

B. Implementation Details

We conducted all experiments on two NVIDIA GeForce GTX 2080Ti with PyTorch implementation. All models were trained from scratch using a cross-entropy loss. The training epoch is determined by tasks. The hyper-parameters of Beta distribution used in mixing statistics were empirically set to \( \alpha = 0.1 \). And, we set the ratio threshold \( \tau = 0.7 \) and \( \delta = 0.3 \). With the exception of chromosome classification, all tasks used the Window strategy. The Block strategy was adopted for chromosome classification. More detailed settings are listed as follows.
Binary Classification. We optimized the ResNet-50 [42] with the following settings: SGD optimizer with Nesterov momentum of 0.9; weight decay of $1e-5$; batch size of 64. The learning rate increased linearly from 0 to $3e-3$ at the first 5 epochs and linearly decayed to 0 following a cosine decay schedule. The image was horizontally flipped with a 50% probability and randomly cropped to $224 \times 224$ before feeding into the model.

Multiclass classification. For the chromosome classification task, we ran five times with the same setting of Binary Classification. The CIFAR-10-C and CIFAR-100-C experiments were built based on PIXMIX [7]. SGD with a Nesterov
C. Comparison with Baseline

Two baseline methods BN and IN are introduced since they are the most popular normalization methods. Both of them have demonstrated their effectiveness in improving model generalization. In practice, as we conducted the experiments on two GPUs, the BN is equivalent to GBN [34]. In the following, we first compare WIN with BN and IN. Then, we compare WIN-WIN with these normalization techniques.

momentum of 0.9 was adopted as the optimizer to train the ResNet-18 [42]. The batch size was set to 64. The learning rate was set to 0.3 and decayed following a cosine learning rate schedule. The augmentation policy was the same as Binary Classification. In the experiments of Digit-DG, five ResNet-18 models were optimized for 180 epochs with the following settings: SGD optimizer with a momentum of 0.9; weight decay of $5e-4$; batch size of 64; cosine decay schedule. The code was built based on mixstyle-release [10]. There was no augmentation for the input images.

Image segmentation. We built the code based on DoFE [4] and MONAI [4]. We trained the 5 layer U-Net [43] for five times and optimized the cross-entropy loss with the Adam optimizer. The learning rate was set to $1e-3$ in the first 60 epochs and linearly decreased to $2e-4$ in the last 20 epochs. $\beta_1$ and $\beta_2$ were set to 0.9 and 0.99, respectively. The input images were randomly cropped and resized to $256 \times 256$.

C. Comparison with Baseline

Two baseline methods BN and IN are introduced since they are the most popular normalization methods. Both of them have demonstrated their effectiveness in improving model generalization. In practice, as we conducted the experiments on two GPUs, the BN is equivalent to GBN [34]. In the following, we first compare WIN with BN and IN. Then, we compare WIN-WIN with these normalization techniques.

For the binary classification tasks, we aggregated all datasets of the same task and trained the DeepAll. DeepAll provides a difficulty coefficient and can be served as the upper bound for each dataset [35]. Table I and II present the experimental results of two tasks. Compared with BN, WIN surpassed it for the OOD generalization remarkably (the $m$-cAUC of $+0.185$ on glaucoma detection and the averaged $m$-cAUC of $+0.098$ on breast cancer detection). Compared with IN, WIN led it with $+0.033 m$-cAUC on glaucoma detection and approached it with $-0.001$ averaged $m$-cAUC on breast tumor detection. The superiority of WIN is more obvious for small training datasets (e.g., H1 and H2). Besides, their results on IND data revealed a slight variation. It is insensitive to normalization methods. Taking advantage of WIN, WIN-WIN achieved the best results on two tasks, which improved WIN by $+0.020 m$-cAUC on glaucoma detection and $+0.021$ averaged $m$-cAUC on breast tumor detection.

Multiclass classification is a more challenging task. The superiority of our methods still exists. Table III presents the experimental results of chromosome classification. This task asks the models to classify the input chromosome image into 24 types. Since a few images in RHH are mislabeled by beginners, the distribution shifts appear in the input images and the labels simultaneously. In Table III, RHH→IPMCH denotes training on RHH and testing on IPMCH, and IPMCH→RHH reverses this setting. The accuracy of WIN excelled that of BN by 19.6% and that of IN by 5.8% in RHH→IPMCH. On another setting, WIN was $+7.4\%$ for BN and $+0.3\%$ for IN. Meanwhile, WIN-WIN improved WIN by $+2.4\%$ in RHH→IPMCH and $+0.3\%$ in IPMCH→RHH. Furthermore, we verified our methods on the common benchmark CIFAR-10-C, CIFAR-100-C, and Digit-DG. As shown in Table IV, our methods effectively improved the corruption robustness compared with the baselines. In the experiments of Digit-

### Table IV

Comparison with baselines on the CIFAR-10-C and CIFAR-100-C. Experimental results are reported with the ResNet-50 trained by the original CIFAR-10 or CIFAR-100. IND performance and OOD performance are reported in Top-1 accuracy (%). Accuracy increase ($m$-cAUC $\%$) and mean corruption error ($m$ CE $\%$) are reported for each method. Top results are bolded.

DG, three domains were used for training and one domain for testing. Our methods greatly outperformed the baselines regardless of the target domain (see Table V). WIN and WIN-WIN excelled the IN by the averaged Top-1 accuracy of +3.6% and +8.9%, respectively. It strongly demonstrates that our methods can improve the OOD generalization with multi-source domain data.

In addition to the classification tasks, we investigated the application of WIN on image segmentation. Table VI presents that WIN outperformed BN with an average of +0.038 dice score and outperformed IN with an average of +0.004 dice score on the OC/OD segmentation. This demonstrates once again that our method can improve the OOD generalization with multi-source domain data.

In summary, WIN is a versatile normalization technique for improving the OOD generalization. It significantly surpasses the BN and IN on a number of tasks regardless of training setting (i.e., single source domain or multi-source domains). On this basis, WIN-WIN can further improve it for OOD generalization on classification tasks.

D. Ablation Analysis

In this section, we looked at the options for $\mu$ and $\sigma$ in WIN first. After that, we investigated the effect of the mechanisms behind WIN-WIN. Finally, we presented the analysis of hyper-parameter sensitivity. All experiments in this section were conducted using a ResNet-50 trained with LAG.

First of all, we removed the statistics mixing. Second, we discussed the choice of the statistics $\mu$ and $\sigma$ in WIN. We employed the global mean $\mu$ or global variance $\sigma$ in the third and fourth row of Table VII, respectively. Thirdly, we investigated the area contributed to $\mu$ and $\sigma$ (see Fig. 4). The global computes the mean and variance with all pixels, namely IN. The Block and Pixel compute them with randomly selected blocks or pixels, respectively. The Mask randomly erases a certain region and computes the $\mu$ and $\sigma$ with the remaining pixels. Finally, we perturbed the global statistics in another way, adding the speckle noise (namely the Speckle) [1]. As shown in Table VII, the following conclusions can be drawn: 1) Statistics mixing is beneficial. 2) Only employing one local statistic dramatically degenerates the OOD generalization. 3) Window and Block are the best practice for the local statistics computation. 4) Compared with IN, perturbing the statistics with the speckle noise or other local statistics does not help the OOD generalization.

In WIN-WIN, we removed the statistics mixing and consistency constraint (i.e., the first row of Table VII), respectively. As shown in Table VII, either of them helped the OOD generalization marginally. The best practice is to combine them together since two mechanisms can complement each other well. Furthermore, we imposed the consistency constraint on the features extracted from the penultimate layer using the NT-Xent loss [36]. The gain of consistency constraint still existed but was inferior to the current design $L_{JSD}$.

Fig. 5 shows the results of different hyper-parameters settings. The $m$-cAUC was impacted by the window ratio threshold $\tau$ mainly, but was insensitive to $\delta$ (see Eq. 11).

E. Comparison with State-of-the-arts

The comprehensive comparison with state-of-the-art methods is presented in Table I. All results are reported with the results of ResNet-50 on the glaucoma detection task.

We first compared our methods with several normalization methods. Among these methods, IN [13], BN [14], and GN [24] are the most popular normalization methods, LCN [29], SNR [17], BIN [19], SN [18], IBN-a [15], and IBN-b [15] are incremental studies for IN, and RBN [27] and CNSN [16] are recently proposed methods for improving the model generalization. Overall, these normalization methods did not present any obvious advantages for IND generalization and OOD generalization and our methods significantly outperformed them. It is worth noticing that LCN and CNSN are most relevant to our method. LCN normalizes every feature with the statistics of its neighbors. CNSN proposes the crossnorm which exchanges local statistics and global statistics between channels. Although local statistics are also used in LCN and CNSN, WIN surpassed them considerably (+0.104 $m$-cAUC for LCN and +0.237 $m$-cAUC for CNSN) and this advantage was expanded by WIN-WIN further.

On the other hand, our methods are also relevant to augmentation-based methods. The comparison with these methods also have been conducted using the ResNet-50 with BN, including image-space augmentation (i.e., AutoAugment [8], RandAugment [9], Patch Gaussian [22], randomErasing [39], mixup [40], CutMix [41], AugMix [6], and PixMix [7]) and feature-space augmentation (i.e., manifold mixup [23] and MixStyle [10]). As shown in Table I, these methods showed their superiority on IND data, but in terms of OOD generalization, their effects were negligible or even negative except for RandAugment and PixMix. Overall, our methods significantly outperformed these augmentation-based methods.

Furthermore, it should be noted that SNR, IBN-a, IBN-b, CNSN, Patch Gaussian, AugMix, PixMix, and MixStyle are state-of-the-art methods of domain generalization and adaptation or robustness which improve the OOD generalization with a single source domain. However, our methods significantly outperformed them.
In practice, the training data is a small population of real data, which is smaller in medical images due to the expensive costs for data acquisition and the high diversity caused by operating procedures and imaging equipment. Thereby, the discrepancy between training data and test data from unseen deploy environments is prevailing exists and leads to performance dips. In this paper, we mainly focus on improving the OOD generalization on heterogeneous data which has the same performance dips. In this paper, we mainly focus on improving the OOD generalization on heterogeneous data which has the same performance dips. In this paper, we mainly focus on improving the OOD generalization on heterogeneous data which has the same performance dips.

The normalization technique WIN is proposed to address this problem with free parameters and a negligible effect for IND data. WIN conducts the feature-level augmentation by perturbing the normalizing statistics with stochastic window statistics. With this feature-level augmentation technique, we propose a novel self-distillation scheme WIN-WIN to eliminate the train-test inconsistency and further improve the OOD generalization in classification tasks. WIN-WIN is easily implemented by twice forward passes and a consistency constraint. Extensive experiments demonstrated our methods can significantly and generally boost the OOD generalization across different tasks spanning 24 datasets.

Here, we presented a comprehensive investigation of the properties of the WIN, covering the impacts on IND data and OOD data, the model convergence, and the time costs. To ensure reproducibility and provide insight for subsequent studies, we conducted the experiments on the widely-used OOD generalization benchmark CIFAR-10-C [38]. Fig. 6 and 7 (a) show the t-SNE visualization and the averaged cosine similarity between the raw image and its corrupted versions (i.e., OOD data); (b) training loss curves on CIFAR-10-C; (c) validation loss curves on CIFAR-10-C; (d) time costs per epoch of ResNet-18 on CIFAR-10-C.

In this paper, we mainly focus on improving the OOD generalization on heterogeneous data which has the same labels but different appearances. A simple yet effective normalization technique WIN is proposed to address this problem with free parameters and a negligible effect for IND data. WIN conducts the feature-level augmentation by perturbing the normalizing statistics with stochastic window statistics. With this feature-level augmentation technique, we propose a novel self-distillation scheme WIN-WIN to eliminate the train-test inconsistency and further improve the OOD generalization in classification tasks. WIN-WIN is easily implemented by twice forward passes and a consistency constraint. Extensive experiments demonstrated our methods can significantly and generally boost the OOD generalization across different tasks spanning 24 datasets.

Here, we presented a comprehensive investigation of the properties of the WIN, covering the impacts on IND data and OOD data, the model convergence, and the time costs. To ensure reproducibility and provide insight for subsequent studies, we conducted the experiments on the widely-used OOD generalization benchmark CIFAR-10-C [38]. Fig. 6 and 7 (a) show the t-SNE visualization and the averaged cosine similarity between the raw image and its corrupted versions using the penultimate layer feature of ResNet-18, respectively. Although BN reported the best result on IND data (see Table IV), IN and WIN were better separated for different classes and showed a better invariance (WIN is the best.). In addition, we analyzed the loss curves for BN, IN, and WIN and their time costs. Fig. 7 (b) and (c) show that the model convergence rate of WIN is not inferior to that of BN and IN. For the time costs, we introduced two schemes: WIN (offline) and WIN (online). WIN (offline) caches the window parameters, while WIN...
(online) generates these on-the-fly. According to Fig. 7 (d), $WIN_{(offline)}$ greatly reduced the time cost but was over 47.2% for BN and 46.5% for IN. In a word, despite the longer training time, $WIN$ can be a good alternative to existing normalization techniques, which enhances the feature representations and improves the OOD generalization effectively.

Despite its superior improvement in the OOD generalization, $WIN$ still has a limitation that the window sampling is inefficient for the inputs with a small size. Fortunately, it is no longer a limitation for existing CNNs. Since large input sizes can improve the model generalization [44], existing CNNs commonly use a large input size. As a variant of IN, a reasonable conjecture is that the advantages of IN are also retained in $WIN$. In future work, we will apply $WIN$ to the pixel2pixel tasks (e.g., super-resolution and style transfer) that widely use the IN. Furthermore, since its superiority for heterogeneous data, its use in federated learning is worth digging into thoroughly.

VI. CONCLUSIONS

In this paper, we propose a simple yet effective normalization technique, namely $WIN$, which uses stochastic local statistics to boost the OOD generalization and not sacrifice the IN generalization. Based on WIN, we propose the WIN-WIN to further improve OOD generalization for classification tasks, which can be implemented with only a few lines of code. Our methods greatly address the OOD generalization of heterogeneous data in real-world clinical practice. Extensive experiments on various tasks and datasets demonstrated their generality and superiority compared with the baselines and many state-of-the-art methods.
