Abstract—Machine learning has significantly enhanced the abilities of robots, enabling them to perform a wide range of tasks in human environments and adapt to our uncertain real world. Recent works in various domains of machine learning have highlighted the importance of accounting for fairness to ensure that these algorithms do not reproduce human biases and consequently lead to discriminatory outcomes. With robot learning systems increasingly performing more and more tasks in our everyday lives, it is crucial to understand the influence of such biases to prevent unintended behavior toward certain groups of people. In this work, we present the first survey on fairness in robot learning from an interdisciplinary perspective spanning technical, ethical, and legal challenges. We propose a taxonomy of sources of bias and the resulting types of discrimination due to them. Using examples from different robot learning domains, we examine scenarios of unfair outcomes and strategies to mitigate them. We present early advances in the field by covering different fairness definitions, ethical and legal considerations, and methods for fair robot learning. With this work, we aim at paving the road for groundbreaking developments in fair robot learning.

Index Terms—Robot Learning, Fairness-Aware Learning, Algorithmic Fairness, Responsible Artificial Intelligence.

I. INTRODUCTION

ROBOT learning has advanced tremendously in the last decade. From learning low-level manipulation skills [1]–[3] to long-horizon mobile manipulation tasks [4], [5], and autonomous driving [6]–[8], machine learning has accelerated the advancement in the entire spectrum of robotic domains. Much of this success has been fueled by data-driven learning algorithms, accompanied by massive curated datasets, and the doubling of computational capacity each year. We are also witnessing more and more learned robotic systems performing tasks in human-centered environments as well as alongside humans. Notable areas include robots in collaborative manufacturing [9], agriculture [10], logistics [11], and search and rescue [12]. Along with these technical advances, studying the ethical as well as legal implications and accounting for fairness in machine learning algorithms is growing in concern. Several recent studies in different areas such as natural language processing [13]–[15], facial recognition systems [16]–[18], and risk assessment systems [19], [20] have demonstrated the vulnerability of these algorithms to biases which leads them to exhibit discriminatory behaviors. Nevertheless, fairness remains little explored in the context of robot learning. Robots as social agents can potentially replicate and even amplify human biases such as favoring particular groups of people or disfavoring interaction with specific users, frequently the less represented in the learning process. Fairness in robot learning is a critical area of research that will not only ensure safety and comfort around humans but also enable ethical decision making. Moreover, preventing and diminishing bias is essential for robot acceptance in human environments and under an appropriate legal framework.

Different technical factors during the design, development, and deployment stages influence the robot’s behavior. Unforeseen outcomes such as bias and discrimination require detailed investigation from a multidisciplinary perspective. Learning algorithms can leverage information to obtain an optimized model to perform the required task. At the same time, the learned model can encode bias through different sources such as societal, historical, measurement, and representation bias. Understanding the sources and types of bias in robot learning is crucial for creating strategies towards fairness-aware learning. Additionally, it is essential to determine the requirements to comply with the legal regulations.

The ethical research carried out thus far in robotics studies the consequences of deploying robots in social environments as well as the consequences of interacting with humans. The ethical dimension is part of the practical ethics field and its analysis involves social sciences, philosophy, and psychology. Based on the idea that solutions to bias and discrimination in robotics can not only be technical but also ethical, researchers seek to reflect on how to build fair interactions between humans and robots, the economic and social implications of deploying robots in social settings, and more importantly, what it means for a machine to behave ethically in crowded or personal environments. As a part of practical ethics, ethics in robotics or roboethics is a multidisciplinary field that aims to find practical
ethical solutions to bias and discrimination in robotics. In this survey, we also present the advances made so far in this field and its applications.

In this work, we present an interdisciplinary overview of bias and fairness in robot learning. Our main goal is to provide a comprehensive review that explores technical, ethical, and legal considerations on the topic. We discuss early advances made in this area based on these three fields. We present ethical guidelines, social and legal considerations, and propose a taxonomy of the types and sources of bias and discrimination in robot learning. Furthermore, we present different fairness definitions, metrics, and methods for fairness-aware robot learning. We describe techniques categorized into three levels, each corresponding to the stages in the robot learning process: data-level pre-processing, model-level in-processing, and model-level post-processing. We further classify the approaches into two problems: detection and mitigation. Finally, we also present initial practices for fair robot learning. By compiling the ethical, legal, and technical approaches from this recent research topic, we aim to present an initial starting point for interdisciplinary advances towards fairness-aware robot learning.

II. BIAS AND DISCRIMINATION IN ROBOT LEARNING

From a societal perspective, "bias" can be defined as the tendency to weigh disproportionately in favor or against groups of people causing prejudicial or discriminatory situations. Similarly, in machine learning and AI, bias refers to when a model systematically and unfairly discriminates against certain individuals or groups of individuals in favor of others [21]. Consequently, in various applied contexts, a series of discriminatory situations have arisen due to unintended bias that has affected a large number of people. For example, discrimination based on sex/gender [13], [16], [22], discrimination in algorithms for job recruitment [23], [24], and many other contexts. This issue has led to widespread concern as it contributes to perpetuating historical injustices and inequitable social structures. Thus, researchers from multidisciplinary fields have argued that to prevent biases in machine learning and AI, it is essential to identify its causes. We can observe a similar trend in the field of robot learning. As social robots and other autonomous systems such as self-driving cars are increasingly being developed, it is important to set out for a comprehensive understanding of sources of unwanted consequences [25]–[29]. To recognize possible sources of bias in the field and the possible discriminatory situations, in this section we provide a review that partitions sources of possible algorithmic bias and types of discrimination in robot learning. First, we describe the source of algorithmic bias in robot learning and their types. Second, we characterize the different kinds of discrimination that may occur in human-robot interaction.

A. Sources of Bias in Robot Learning

The sources of bias from data and algorithms have been primarily studied in fields such as machine learning and AI. Recent works have analyzed data biases [30]–[32] where they present complete lists of the different types of biases and their corresponding definitions. Whereas, in robot learning, there have been no detailed and extensive studies on the sources of biases. The presence of robots in social contexts has started to generate studies about the possible sources of bias and its impacts. Recent studies regarding biases in social robotics highlight potential sources of bias in this field, as well as their consequences [29], [33]–[36]. These studies demonstrate the critical need to evaluate human-robot interaction as a socio-cultural activity. Therefore, recognizing the benefits or prejudices that it may generate is an important part of responsible development. Biases can be caused by multiple factors such as bias in the data, bias in user’s behavior, and bias from training models. In the following, we categorize the types of biases in robot learning and their effects on the functioning of robots as well as the effects on society.

1) Evaluation Bias: arises during the evaluation of algorithms. This assessment is typically carried out using benchmarks that disproportionately and incorrectly measure the performance of algorithms. It is also associated with the evaluation of bias in robot decision making [37]. For instance, bias can be acceptable if its use is properly justified or unacceptable if it replicates, promotes, or amplifies social discrimination. In [37], the authors present an example of evaluation bias using an algorithm that implicitly incorporates social dynamics through a learned model to guide a mobile robot to a destination. The algorithm subdivides the personal space of people into the human-robot interaction zone and a private zone in which the robot will not be able to navigate [38]. As the goal of the algorithm is to choose an optimal navigation strategy, the bias leads to robots having a greater distance with women than with men. In this paper, the authors argue that there are no reasons to justify this gender bias that affects the robot’s interaction with women.

2) Representation Bias: occurs as a result of how developers define and sample from a population using, for example, the geographical area. For instance, [39] shows such a simulated scenario where a rescue robot uses geographic population data from the census to search for victims who might need medical assistance after an earthquake. As the spatial distribution of the population within the census data is based on variables such as age, ethnicity, and gender, the non-uniform distribution leads to bias in the variables used for path planning, resulting in biased decisions that can affect certain groups of populations more than others. In such extreme cases, representation bias leads to inequality which could put people’s lives at risk.

3) Aggregation Bias: occurs when erroneous conclusions are made for one group of people based on observations made from other groups [30], [31]. For example, recent work has demonstrated evidence of bias in the pedestrian recognition system of self-driving cars [40]. Although deep learning approaches for object detection have enabled significant advances, the lack of diverse data from some populations such as people of color, causes them to be misidentified. This can be primarily attributed to the fact that technological development and data collection takes place in certain geographic areas where communities have lighter skin tones, thus affecting all other diverse groups of people. In [41], the authors present results from experiments of eight AI models used in the state of the art object detection systems and propose the concept of “predictive inequity”
for detecting pedestrians with different skin tones. Similar works have shown the presence of age and gender bias in pedestrian detection algorithms of robots [42]. In the social sphere, aggregation bias not only harms the acceptance of technological systems but also risks the lives of people. From the technological point of view, it leads to the failure of the system and its disuse.

4) Measurement Bias: arises when the data collected for training significantly differs from the data obtained during real-world deployment or when defective measures cause skewed data [30], [31]. If a particular feature in the data is misused or measured incorrectly, this can lead to biases in robot decision making. For instance, care robots should be made accessible and usable by a wide range of populations with protected characteristics. In this case, the wider input and output options must be compatible with the people that the robots will assist, since an error in the sensor measurement will lead to various detriments to users [43]–[46].

5) Sampling Bias: arises from how data is selected and does not achieve adequate randomization, making some members of the population or certain environmental characteristics less likely to be included in the sample [47]. As a result, the inaccurate distribution of training data does not resemble the real environment where robots will be deployed. As each population and social environments have its characteristics, the algorithms in robots should be able to recognize these characteristics. In [48], the authors present an example of sampling bias in self-driving cars. They exposed a hypothesis where researchers are trying to create an autonomous driving car that can operate at any time of the day. Nevertheless, the training data used is based on daylight video, as a consequence, its deployment can cause fatal accidents at nighttime. This problem has been analyzed in several works that show that sample selection bias is ignored in standard estimation algorithms [49]–[52]. In [53], the authors show that the problem occurs quite frequently, given that not only data is collected in a biased manner, but the deployment is often performed on a more general target population.

6) Historical Bias: refers to the bias arising from socio-cultural inequalities that are contingent on history and are represented in historical data used for training algorithms. This type of bias originates from preconceived notions or prejudices that have unwanted characteristics. Even if data is correctly measured and sampled, learning robotic skills and behaviors from this historical real-world data can lead to unintended and unforeseen consequences [54], [55]. Moreover, prejudices from the past can be transmitted to the future through the robots that are then deployed in human environments. For example, in [56] the authors present an example of how historical bias can be transferred through algorithms in robotics. They argue that a package delivery robot that has been trained with similar spatial data used in other machine learning settings such as predicting a defendant’s future risk or misconduct can behave unfairly while deciding the areas of the city considered as safe or unsafe. Historical bias can lead to similar events against communities that have been historically discriminated against. Therefore, it is imperative to ensure that the presence of robots in public spaces does not repeat, perpetuate or even increase stereotypes that society seeks to remove.

7) Developers Bias: Biases arise not only due to data but also come from the developers or creators. This type of bias can be categorized as implicit and explicit bias. Implicit bias refers to software or robot engineering choices (e.g. feature selections or design choices regarding the appearance of a robot) that are not explicitly motivated or discussed but are induced by developers acting on cognitive biases influenced by their individual beliefs, actions, cultural and societal context. These biases indirectly affect how models are adapted [57]. Whereas, explicit bias is consciously put into models by their creators, sometimes with the explicit aims to reduce certain types of inequalities or under-representation in data samples. Recent research [58], [59] has also exposed that explicit bias often comes from a lack of diversity in research groups in robotics. Consequently, a small homogeneous group of people is the ones who decide the type of data, societal and demographic characteristics and populations to be analyzed.

8) Algorithmic Bias: Algorithms play an important role in the functioning of robotic systems, and algorithms themselves can amplify biases in the data. The study of algorithmic bias is concerned with algorithms that reflect systematic and unfair discrimination. Some researchers [60] argue that algorithms are neutral and unbiased as algorithms are treated as black-boxes. However, algorithms can acquire human biases [61]. Ethical research advocates for transparency in algorithms. In [48], [62], the authors provide a taxonomy of different types of possible algorithmic bias and their impact on autonomous systems. They use this taxonomy to distinguish between algorithmic biases that are neutral and those that need to be addressed. This work also shows that there are algorithmic adjustments that developers can use to compensate for problematic bias and show that solutions also require adjustments by the agent, whether a human or an autonomous system, who uses the results of the algorithmic bias. Therefore, there is no one possible solution to algorithmic bias.

9) Societal Bias: happens when judgments or actions of people influence the behavior of robots and the decisions they make. Specifically, this type of bias arises from learning interaction behavior from data. The goal of learning from demonstration is to have a robot learn from watching a demonstration of the task to be performed [63], [64]. When these robots are deployed in the real world, they can indirectly learn biases that directly come from society [21]. They also reflect the personal biases of individuals that interact with the robot. This is particularly important because robots are not intended to replicate unethical aspects of society. Their participation in society is to be machines that help people to perform tasks or make their lives easier. To fully accomplish this task, social biases must not influence their behavior.

Based on the analysis performed in this section, it can be argued that the well-known sources of bias in machine learning are linked to the sources of bias in robot learning. Moreover, the sources and their consequences are also diverse. As opposed to learning in other fields, as robots physically interact with humans, there are more complex sources of bias that can arise. At the same time, this interaction influences social structures, justice, and equality, as well as changes in society itself. Finally,
it is important to note that human-robot interaction poses a new challenge to what we understand by interaction and how we want to build fair interactions.

B. Types of Discrimination in Robot Learning

Discrimination is not a static phenomenon, and its causes and manifestations vary in a social context. Its resilience rests on the self-perpetuating nature of power and hard-wired bias carried by individuals and groups of people. Therefore, it denies opportunities to members of one group that are feasible to other groups. In robot learning, on the other hand, discrimination is the result of bias and its consequences are linked to discriminatory behaviors in robots. This makes the robot more efficient for a certain group of people than others. Since robots are expected to be in important human scenarios [65], developers need to consider the possible types of discrimination. Importantly, there are many potential ways in which robots can be taught to do something immoral, unethical, or just plain wrong. If developers are aware of the potential discriminatory scenarios, then they can account for how the robot should interact fairly and equitably. Although the possible discrimination scenarios in robot learning have not yet been studied in-depth, in autonomous mobile robots such as self-driving cars, there is recent work in this area [66]–[70]. Nevertheless, the types of discrimination can be extrapolated to other robot learning applications such as assistive and service robots. In the following, we describe the types of discrimination that may occur in robot learning as a consequence of biases.

1) Direct Discrimination: occurs when robots treat people unfairly considering their protected characteristics [71]. In this case, discrimination arises from procedures that explicitly use sensitive attributes such as race, gender, socio-economic status, geographical area, etc., for tailored autonomous decision making. In self-driving cars, direct or intentional discrimination concerns seemingly justifiable, even permissible, forms of active discrimination that involve justified benefit to a reduced group of people [67]. However, protected characteristics should not be used by the algorithms to distinguish individuals. Research in this area has shown that equality of opportunity is a helpful concept to avoid discrimination in autonomous vehicles [69].

2) Indirect Discrimination: arises when robots do not explicitly use protected characteristics to guide their decision making, but instead rely on the way they interact and classify different groups of individuals according to their protected characteristics [71], [72]. In machine learning, indirect discrimination has caused, for example, certain groups of people to be excluded from a job or denied credit. In [73] the authors present an example of how a machine learning system that predicts who is eligible for a bank loan and who is not can generate indirect discrimination. They showed that even if the training data do not contain information about protected characteristics, the machine learning system learns that people from certain postcodes were likely to default. Here it seems reasonable to assume that there is no discrimination. However, the postcode may correspond with racial origins. In this case, the decision is causing harm to people of certain racial origins. A similar scenario can occur in robot learning. For instance, in [74] the authors present the example of a robot in charge of conducting job interviews. Their purpose is to present a method to avoid possible bias named fair proxy communication. This form of communication seeks to eliminate implicit biases that produce indirect discrimination by recognizing them, to inform new possible interventions that will reduce the possible harm.

3) Explainable Discrimination: occurs when developers use protected characteristics to influence robot decision making to achieve fair outcomes [72], [75]. One of the most important abilities that a personal robot requires when interacting with humans is the ability to discriminate among them to achieve welfare [76]. However, these personal characteristics can not be the cause of segregation and their use must be justified. In [77], the authors present an interesting point of view about explainable robotics. They argue that to ensure robots work safely and reliably with humans, it is essential to create methods and algorithms for generating explanations. These explanations will allow robots to operate in different scenarios and communicate their decisions to humans, which will further facilitate effective human-robot interaction.

4) Unexplainable Discrimination: refers to unjustified and unexplained discriminatory robot behavior toward a group, especially minorities. More specifically, it occurs when robot decision making is based on the user’s protected characteristics such as gender, race, disabilities, religion, etc., which are unexplained. This type of discrimination can be illegal in certain settings [75], [78], [79].

III. LEGAL AND FAIRNESS CONSIDERATIONS IN ROBOT LEARNING

In social science and philosophy, ethics is considered as a complex system of moral principles and rules that allows to evaluate the actions of people as good or bad [80], [81]. Whereas, ethics in robotics [82] is associated with questions such as how to achieve responsible robot systems, what are their potential risks and how to avoid them, what are the robots’ social and economic implications, among others. In recent years, several recent works have proposed fairness and legal considerations to achieve ethical robots. In this section, we present an overview of the current research carried out in this area. We first present a general analysis of current developments in the emerging area of roboethics and subsequently, we focus on the two fields of roboethics: fairness in robot decision making and legal considerations in robotics.

A. Roboethics

The interaction between humans and robots in social and personal environments has led to extensive studies on the ethical implications concerning the design and use of robots, and robots’ moral behavior. It is essential to take ethical considerations into account while developing robots that will interact with humans as this will reduce possible future risks, such as potential cases of discrimination and segregation. All these issues gave rise to the emergent field of Roboethics. This denotation was used for the first time at the Workshop on Roboethics organized in conjunction with the 2005 IEEE
International Conference on Robotics and Automation [83], [84]. Research in roboethics involves questions on how to achieve safety and avoid errors since robots can cause fatal accidents; law and ethics linked with questions associated with a responsibility for resulting harm; ethical considerations in robot development, commercialization, and use; fair robot decision making and privacy, robots social impact [85], [86], human-robot interaction, and moral robot behavior. In particular, the field covers the entire range of ethical issues connected to robot moral design, operation, and use [87]. It is important to mention that analyzing aspects of robot consciousness, free will, dignity, and emotions are not part of the current scope of the field [79], [88]–[90]. Moreover, there are many other questions in this field related to issues such as how to computationally model human moral reasoning in robotic agents, and whether human moral reasoning should be computationally modeled in robotic agents [91].

Roboethics as well as other ethical studies are considered as a broad field framed in practical ethics that defines the behavior of robots based on values and norms taken from society and analyzed by moral theories such as deontology, consequentialism, egalitarianism, utilitarianism, virtue ethics, etc. These perspectives influence the design of robot behavior and determine how robots as social agents should make moral decisions based on judgments about actions. Deontology is the normative ethical theory that argues that the morality of an action should be based on whether actions themselves are right or wrong under a series of determined rules [92]. Specifically, deontology principles convey in concrete terms which actions are ethical or unethical. One of the main characteristics of this theory is the principle that actions or inactions are crucial, not their consequences. Similarly, in robotics, Deontology refers to the design of the moral behavior of robots from a finite set of (algorithmic, programmable) rules or ethical standards [85]. Specifically, it concerns how the characteristics of the ethical behavior of robots are selected and computerized. In [93], the authors present an applied form of deontology that goes beyond the design of the robot’s moral behaviors and its computerization. They examine how robots can serve as moral advisors for humans based on deontological approaches and argue that robots can encourage humans to make honest decisions under the premise that acting ethically is more important than the consequences of their actions. They performed human-robot interaction experiments in which the robot’s task was to encourage people to make fair and honest decisions by offering moral advice. As a result, they show that advice based on deontological methods tends to be more effective. On the other hand, Consequentialism is a class of normative ethical theory based on the principle that the consequences of the actions are the basis for any judgment about its rightness or wrongness, and not their acts themselves. In robotics, this theory is presented as the analysis of the identity of the agents that cause certain actions and the effect of these actions in social environments. The fundamental difference between deontology and consequentialism in robotics is that the first theory is used to program the ethical behavior of robots, and the second is used to analyze the consequences of their behavior.

Similarly, Utilitarianism and Egalitarianism in roboethics refers to the design of fair robot decision making. Utilitarianism is connected to consequentialism. According to this moral theory, an action is right if it promotes happiness or pleasure of the greatest number. In robotics, utilitarianism offers a method for deciding whether an action is moral or not. In other words, Utilitarianism in robotics refers to predicting various actions that robotic systems will perform, estimating the benefits of these actions, and choosing only those actions that maximise well-being. Utilitarianism is especially popular as it enables quantitative evaluation of welfare or damage that robots can produce [94]. Finally, in [95] authors proposed an interesting new approach to design ethical social robots called Virtuous Robotics. These robots have the task to help people reach a higher level of moral development through virtue ethics approaches. As a result, they justify the use of virtuous robotics illustrating how these systems allow humans to discriminate between positive and negative applications of robotics systems.

Egalitarianism is the view that all individuals or social groups should have equal opportunities. In robotics, egalitarianism is used to design fair algorithms that diminish inequality or discrimination in robot decision making through equality [39], [96]. However, this concept is often criticized for failing to account for factors that people cannot control and morally justify indirect inequality. Not all people are equal and have equal conditions, so treating them all equally can cause some to obtain more benefits than others. Egalitarianism is also connected with prioritarianism in robot decision making.

Another significant point is that roboethics aims to ensure that responsible robot development and robot decisions are consistent with a set of universally shared moral values such as respect human dignity and human rights, equality, justice, equity, benefit, respect for cultural diversity and pluralism, non-discrimination and stigmatization, social responsibility, etc. Following this scope, the EURON Roboethics Atelier project [97] created by the scientists from the European robotics community aims to create guidelines for building responsible robots through two strategies. First, the creation of a roadmap designed to analyze opportunities to build and use advanced robot technology. Second, to measure the ethical issues involved in the development of robots, to understand the ethical problems, and to promote interdisciplinary research. The project aims to create an ethical agenda for the near future. In addition, there is a special interest to explore how ethical systems and behaviors may be programmed into social robotics applications. Researchers in the project affirm that robots should be programmed with the ability to navigate in human spaces without committing unethical actions and or uncivilized behavior [98].

As robots are being developed for a wide range of human-robot interaction applications such as care or rehabilitation, the analysis of the interaction between humans and robots within these scenarios to understand what makes people trust, become emotionally attached to, and socialize with robots is a critical factor [99]–[101]. Moreover, ethics has always been analogous to the pursuit of happiness. Keeping with this argument, researchers in roboethics also study the contribution that robots make to human happiness within the framework of
virtue ethics.

In [125], the authors from different fields propose five standards for the creation and use of robots to achieve responsible robotics, these standards are:

- Robots should not be designed as weapons, except for national security reasons.
- Robots should be built and operated in accordance with current legislation.
- Robots are products that should be designed to be safe and secure.
- Robots as manufactured artifacts should not be used to exploit vulnerable users.
- Humans are responsible for any robot actions.

The aforementioned principles were created to explore what steps should be taken to ensure that robotics research can be integrated into society without causing harm.

B. Fairness Definitions in Robot Learning

Much of the literature on fairness in robot learning is motivated by the concern that high-impact decisions made by robots may have negative consequences or unfair distribution of the tasks in human-robot interaction. Consequently, most of this work is focused on determining the meaning of this concept and how it should influence robots’ behavior and decisions. However, similar to robotoethics, fairness in robot learning is presented as a concept that can have different meanings and interpretations. In this section, we present some of the research conducted thus far on fairness in robotics.

In [102], the authors study factors to achieve social interaction such as fair decisions in robot behavioral design. The authors argue that fair decision making improves trust, social functioning, and the performance of a team. Consequently, they present an overview of current design characteristics to develop optimal human-robot interaction and show that fairness is recognized when the decisions of robots comply with the principles of organizational justice. This principle is associated with the manner in which decisions are made, their representation, and distribution. Further, this principle has four dimensions: distributive, procedural, interpersonal, and informational justice. Distributive justice refers to fair distributive results or decisions between stakeholders. Procedural justice is associated with fair decision making procedures through aspects such as consistency, lack of bias, accuracy, correctability, and morality. Interpersonal and informational justice is related to robot communication. The first describes that robot behavior is perceived as fair if it is respectful, polite, and dignified. The latter relates to transparency in robot decisions. Finally, the authors explain that research in this area has included the organizational justice principle in the robot’s decision using fair algorithms.

In fair robotics, fairness is also generally connected to the cooperative task between humans and robots. In [103], the authors experiment to understand a human teammate’s perception of fairness during a human-robot collaborative task where certain tasks leverage the robot’s strengths and others leverage the human’s. In particular, they showed that fairness in the human-robot teamwork must be appropriately designed.

Further, fairness is the basis of trust and team effectiveness. Additionally, within the study, they investigate the effects of fluency (absent vs. present) and effort (absent vs. present) in collaborative tasks. The results of this experiment show that effort and fluency help in achieving fairness without making any trade-off with efficiency. The authors also conclude that in the collaborative task, participants’ fairness perception is influenced by team members’ skills level and task type. Associated with this, they propose three notions of fairness in human-robot teamwork: equality of workload, equality of capability, and equality of task type. Similar work was presented in [104] where the authors show that to achieve fair interaction between humans and robots, these machines have to perform a wider range of tasks. More recently, in [105], the authors present a novel approach for social and fair behavior learning in human-robot collaboration based on recognizing anti-social and unfair behavior. They argue that in order to avoid dilemmas in specifying and modeling sociability and fairness in robotics, learning to avoid unfair behavior can be an optimal way to achieve fair human-robot interaction.

In robotics, fairness is primarily connected with the cooperative relationship between humans and robots and how the tasks are distributed [106]. However, more research is needed in this field that goes beyond cooperative work. Therefore, it is also necessary to analyze the environments in which both humans and machines will be present, regardless of whether there is direct interaction.

C. Legal Considerations in Robot Learning

The increasing real-world applications of robotics have given rise to ethical and political discussions, and policy efforts to regulate the trajectory of these technologies. There is significant public discussion about artificial intelligence ethics, and there are frequent discourses from regulatory bodies that the matter requires a new policy, especially due to the autonomy of these systems. Governments around the world, especially the United States of America, the European Union, Russia, and China, consider the development of artificial intelligence and robotics as economic and policy priorities, mainly because these systems can result in unfair and discriminatory behavior that can reinforce social inequalities [107]–[112]. However, to draft policies on this subject is a complex task due to infrastructure taxation, goodwill statements, the regulation by various actors and the law, and funding [82], [113]. Towards this effort, governments, parliaments, associations, and industry have presented proposals to regulate robot creation, commercialization, and use [97], [114]–[118]. As a consequence, there are promising advances in the subject. Most of these guidelines analyze aspects such as liability, warfare, safety, discrimination, fairness, and human-robot interaction. Notably, regulating the behavior of those working in the robotics industry is also one of the main features of these guidelines [115]. In [82], the authors argue that those who work on ethics and policy in robotics tend to overestimate its impact and threats and underestimate how far current regulation can reach.

There are normative frameworks and legislations on fairness and non-discrimination. Most importantly, there is a human
right to equality and non-discrimination which is codified, for example, in Art. 26 International Covenant on Civil and Political Rights (ICCPR) [119] and in regional human rights treaties, such as Art. 14 of the European Convention on Human Rights (ECHR) [120]. The term equality can imply formal and/or substantive equality. Formal equality means primarily procedural equality, e.g. equality before the law and equality of the law [121], [122]. Substantive equality implies equality of opportunities and equality of results, some call this equality through the law [121], [122]. The human right to equality and non-discrimination primarily obliges states to grant equality before the law and equality of the law, e.g. the law should not discriminate. However, states may also have positive obligations to protect individuals from discrimination by regulating private conduct, especially regarding employment, education or private activity in a quasi-public sector [121], [123], [124]. It is important to note that states may also take affirmative action (positive discrimination) to overcome structural discrimination and establish equality of opportunity or equality of results (e.g. by introducing quotas). Considering the case law of the Human Rights Committee and the European Court of Human Rights, such forms of (positive) discrimination do not constitute a violation of Art. 26 ICCPR or Art. 14 ECHR, as they can be objectively and reasonably justified, i.e. the legitimate aim is to establish de facto equality [123], [124]. There are several international conventions that specify the obligations of states with regard to discrimination based on protected characteristics, e.g. the International Convention on the Elimination of All Forms of Racial Discrimination (ICERD) [125] or the Convention on the Elimination of All Forms of Discrimination against Women (CEDAW) [126].

States have adopted legislation to protect individuals from discrimination, for example, the Civil Rights Act of 1964 in the United States or the Council Directive 2000/78/EC of the European Union regarding employment [127]. These laws could limit the discriminatory use of robots in employment settings. With regard to anti-discrimination law in the United States, e.g. the Civil Rights Act of 1964, researchers argue [128] that there is a gap between the definitions of fairness in machine learning and the actual legal concepts on which they are supposed to be based. This gap is due to the misunderstanding of legal concepts in the field of machine learning. The authors point out that while discrimination in machine learning is related to a false outcome, US anti-discrimination law defines discrimination not through outcome but causality and intent, which is difficult to apply to non-human decisions. Regarding the employer’s decision to use the robot, a discriminatory intent can be difficult to prove because the employer will often not know that a discriminatory effect exists [129]. Disparate treatment (direct discrimination) will thus be difficult to prove in US anti-discrimination law. Anti-discrimination law also protects against indirect discrimination (disparate impact), i.e. a treatment that affects people differently without considering protected characteristics, which is particularly relevant in algorithmic and robot learning because of the unintended discriminatory effects [123], [124]. In anti-discrimination law in the United States and the European Union a disparate impact (indirect discrimination) can be reasonably and objectively justified [122], [128]. In [122], the authors argue that the legal requirements to justify indirect discrimination imply that minimum methodological standards must be met in machine-learning (or robot learning). However, anti-discrimination law currently covers only certain settings, primarily employment, and there could be regulatory gaps regarding the use of robots in other circumstances. Data protection law could provide for more comprehensive standards. Data protection law regulates the collection and processing of personal data. The General Data Protection Regulation (GDPR) of the European Union is one of the most advanced legislations [130]. As outlined above, data sets in robot learning are mostly anonymized, and the protections for processing personal or sensitive data do therefore not apply [131]. Art. 22 GDPR sets requirements for automated decision-making. The meaning of this provision is still disputed [122], but it sets some standards and limits which could be relevant for robot learning.

Existing legal provisions set standards regarding equal treatment and non-discrimination. These standards need further elaboration, especially regarding the question of whether the current criteria for determining discrimination can reasonably be applied to robots and whether and how discrimination can be justified. Interdisciplinary work combining technical and legal considerations is needed to develop an appropriate methodology for robotic learning and to evaluate whether adapting existing legal concepts and/or adopting new legislation is necessary. Considering approaches for the regulation of AI might be useful in this regard. Several ethical guidelines regarding artificial intelligence have been adopted, for example, by the OECD [132]. They are also concerned with non-discrimination and establish principles that might be useful for fairness in robot learning, such as transparency, explainability, safety or security. These principles can also be found in the draft proposal of the Artificial Intelligence Act of the European Union (e.g. Art. 13, 15, 52) [133]. The Draft Act establishes in Art. 10 requirements regarding data and data governance for high-risk AI, e.g. Art. 10 (3) states: “Training, validation and testing data sets shall be relevant, representative, free of errors and complete”.

Another important aspect of robot regulation, besides non-discrimination, is accountability for damage caused by a robot, which is addressed, for example, in the European Parliament’s resolution in “Civil Law Rules on Robotics” [134]. Importantly, transparency, as a mechanism to explain robot behavior and decision making clearly, is presented as a fundamental tool to achieve accountability [135], [136]. This issue has already largely been discussed in the context of autonomous driving cars [137]–[140], and some conclusions might be drawn from this for robot accountability.

One also needs to consider that there might be regulatory dilemmas in robotics. In [114], [141], the authors analyze four regulatory dilemmas in robotics, namely how to keep up with technological advances, how to balance innovation and human rights protection, whether to conform to existing social norms or to create new ones and how to balance efficiency with techno-regulation. In each of these regulatory dilemmas, the authors focus on liability, privacy, and autonomy, which often feature as the major issues requiring regulatory attention. In
with technological advances. In law, this is known as the susceptibility to finding over-associations to features related to bias. In addition to data-related bias, learning approaches are and even amplify unfair situations explicitly or implicitly samples. Current learning algorithms can significantly replicate containing human biases or datasets without fairly represented models that explain the observed behavior.

A typical and simplified robot learning process consists of three main stages: dataset construction or demonstration data collection, model training, and inference as shown in Fig. 1. We previously identified bias at three levels in the robot learning process throughout the different learning techniques: data level, model level, and rectifying level. We use these stages prone to categorize the explored methods for fair robot learning.

**A. Fairness Metrics**

Measuring fairness in learning algorithms is a challenging task that remains an active area of research. Currently, there are no conventional fairness definitions or metrics for robot learning. Nevertheless, generating a single metric that satisfies fairness across social situations, cultures, and diverse individuals is unfeasible. Robots operating in real-world social scenarios

**IV. METHODS FOR FAIR ROBOT LEARNING**

So far, we have presented the ethical and legal implications of robot learning from a fairness perspective. In this section, we discuss how unfair outcomes can arise in robot learning from a technical perspective. After identifying the bias susceptible robot learning stages, we present methods for detecting and diminishing bias. Additionally, we show evaluation methods to access the bias correction.

Most robot learning algorithms follow the data-driven paradigm. This allows robots to automatically learn from data using guidance or supervision to optimize the models for specific tasks such as navigation. For instance, supervised learning approaches utilize datasets containing data and the corresponding annotations. This annotated data is then used to learn a model that generates the desired output. Other learning approaches such as reinforcement learning and imitation learning, do not require the labeled input-output data pairs. Instead, these approaches use the experiences of an agent performing actions as the learning guidance. In reinforcement learning, the agent takes actions in an environment, and a reward function punishes or encourages the decisions in order to maximize the notion of cumulative reward to obtain an optimal model. With inverse reinforcement learning approaches, imitation learning aims to optimize a model to generate actions that imitate an example behavior. In this case, instead of using a reward, the reward function is inferred from a set of expert examples. The idea is to mimic by recovering a cost function that explains the observed behavior.

Since these approaches use the data-driven paradigm, the first natural source of unfair results in robot learning is data containing human biases or datasets without fairly represented samples. Current learning algorithms can significantly replicate and even amplify unfair situations explicitly or implicitly included in the utilized data, which constitutes a data-level bias. In addition to data-related bias, learning approaches are susceptible to finding over-associations to features related to a particular characteristic such as race, age, or gender and the prediction task, which constitutes a model-level bias. Furthermore, the intermediate representations of learned models are challenging to interpret, and the models are often considered black-boxes where understanding the inside representations is not a priority. Therefore, learned models have challenges regarding explainability, leading to issues in determining the reasoning behind biased outputs.

Despite recognizing fairness as an essential value for human safety and confidence around robots, fairness in robot learning is still in the early stage of research. We find fairness concepts only included in a few cases in the different learning stages through all learning techniques [37], [39], [42], [69]. More considerable research advances exist in algorithmic fairness [143]–[145]. Such an example is algorithmic fairness in natural language processing, where discrimination is more explicit, and techniques for prevention and correction are more explored [14], [15].

In the specific case of robotics, ethical scenarios are studied in the area of autonomous driving, given the high interest in this topic and the general concern regarding safety. For instance, in autonomous driving, creating pedestrian detection models that are robust throughout diverse color skin has taken recent interest [41], [146]. Moreover, different works in this topic analyze the social implications, moral dilemmas, and the requirements that build the confidence needed to incorporate autonomous vehicles in real-world scenarios and safely operate around humans [147]–[153]. Some other works in robotics concentrate on the physical characteristics and the assigned task that a robot should perform, and provide the ethical implications [154]–[156]. Differently, in this paper, we collect the methods used to measure fairness in learning models and include fairness awareness in the context that can be applied in different stages of the robot learning process. Since learning algorithms constitute such an essential component in robot development, this work aims to provide an initial guide specifically for learning methodologies that contribute to widely benefiting humans across their demographics, characteristics, and diversity.

A typical and simplified robot learning process consists of three main stages: dataset construction or demonstration data collection, model training, and inference as shown in Fig. 3. We additionally survey different metrics proposed to measure model fairness.
must account for different perspectives to fulfill human safety and comfort standards. Thus far, multiple fairness metrics have been studied and proposed in the context of computer science and algorithmic fairness. These metrics, including individual fairness and group fairness, can also be used in the context of robot learning. Therefore, individual fairness involves similar treatment, requiring, for instance, that similar individuals obtain similar quality interaction with a robot or obtain similar performance quality. In group fairness, the goal is to analyze the robot’s actions across subgroups in the data, usually concerning sensitive attributes. Then, the actions or quality performance is compared across these groups.

Selecting the right fairness metric is an additional open challenge for fair robot learning. Not only can the fairness metric change across specific tasks, but it is also goal and context-specific. Besides the social-related difficulty, it has been shown that it is not feasible, from a technical point of view, to simultaneously satisfy all definitions of fairness [157]. An interdisciplinary approach supported by the definitions and explanations helps select the appropriate fairness metric and further interpret it. Accurate metric interpretation is a key to localizing sources of bias and how to mitigate the effects. Additionally, fairness metrics should be diverse, dynamic, and easily adaptable to novel social scenarios [158]. After evaluating different fairness metrics, [159] provides a set of warnings when selecting the appropriate approach. The authors found that in the cases where accuracy should be equal across groups of interest, most metrics are appropriated, and the interpretation is straightforward. Nevertheless, on the contrary case, such as in many robot scenarios, fairness metrics interpretation is challenging, and the intervention of human experts might be required. Some fairness metrics that can be used in robot learning are Individual Fairness, Demographic Parity, Equal Opportunity or Equalized Odds, and Predictive Quality Parity. In the following, we define these metrics and include examples in the context of robot learning.

1) Individual Fairness: is based on providing similar outcomes to similar individuals. Therefore, it measures the similarity-distance between the individuals and the distance between the possibilities of obtaining outcomes assigned to them. Then, individual fairness estimates how distanced they are [96]. This can be measured by comparing input and output distributions with a statistical distance. However, previous work points out that individual fairness provides a problematic definition of fairness. The main concerns include the insufficiency of similar treatment and finding suitable similarity metrics [182].

2) Group Fairness: is also known as statistical fairness, and it is widely used as a fairness definition [183]. Different group fairness metrics are proposed based on sub-groups, usually chosen with sensitive attributes such as race or gender. These metrics use terms such as the rate of false positives (FPR) and false negatives (FNR). FPR is the probability of falsely obtaining a positive result and it is calculated as:

$$FPR = \frac{FP}{FP + TN}, \quad (1)$$

where FP and TN are the False Positives and True Negatives, respectively. Similarly, FNR indicates the probability of incorrectly assigned as negative and it is defined as:

$$FNR = \frac{FN}{FP + TN}. \quad (2)$$

By quantifying the incorrect results across different subgroups, the following group fairness metrics indicate the presence and proportion of disbalance in the intended functioning of the algorithm.

- **Fairness Through Unawareness**: assumes that by omitting explicit information from sensible attributes, we can obtain a fair learned model [162]. With fairness through unawareness, we expect that the users in the subgroups $A = 0$ to have an equal probability of being assigned the same model prediction distribution as the entire users, such that:

$$P(\hat{Y}|A = 0) = P(\hat{Y}). \quad (3)$$

Nevertheless, it has been shown that ignoring the sensitive attributes does not guarantee that the learned model is fair [165]. Even though this comparison is difficult to achieve, it is usually a good practice to prevent the inclusion of sensible attributes into the learning process unless a human expert has a valid reason to do so.

- **Demographic Parity**: is a metric that assesses whether robot decisions have a similar effect across different groups of people. It is satisfied if the results of a learned model do not depend on protected attributes [163], [164]. It is formally defined as:

$$P(\hat{Y}|A = 0) = P(\hat{Y}|A = 1). \quad (4)$$

With demographic parity, we aim that the subjects in the different groups $A = 0$ and $A = 1$ have an equal probability...

of being assigned to a correct positive model prediction $\hat{Y}$. Therefore, it promotes the True Positive Rate (TPR) to be the same for each subgroup such that:

$$TPR_{(A=0)} = TPR_{(A=1)}.$$ (5)

In robotics, this can be correct functioning, completing the main goal, or adequately interacting with a user. For instance, a robot ideally interacts equally with users regardless of their skin color. Therefore, demographic parity requires an equal proportion of positive robot performance throughout the groups of interest. However, achieving this absolute equal proportion in the real world is not feasible. Instead, an approach that aims to minimize the TPR gap is accepted, or a threshold $u$ is accepted such that:

$$\frac{P(\hat{Y} | A = 0)}{P(\hat{Y} | A = 1)} \geq u,$$ (6)

where, as disparate treatment, it is usually accepted that $u = 80\%$. Demographic parity is helpful for reasoning about the inequities and monitoring the robot decision making process. However, the main risk in using demographic parity as a fairness definition is a generalization. For instance, if a user with a disability requires personalized interaction, the overall fairness evaluation with demographic parity will be affected [165]. Therefore, satisfying democratic parity does not necessarily certify a fair robot model.

- **Equalized Odds**: requires the positive outcome to be independent of the protected class $A$, conditional on $Y$ being an actual positive and it is defined as [165]:

$$P(\hat{Y} | A = 0, Y = y) = P(\hat{Y} | A = 1, Y = y), y \in \{0, 1\},$$ (7)

This metric compares both the true positive rates and false positive rates for different subgroups of interest such that:

$$TPR_{(A=0)} = TPR_{(A=1)},$$ (8)

$$FPR_{(A=0)} = FPR_{(A=1)}.$$ (9)

This is a very strict fairness metric since it aims to minimize the gap in both TPR and FPR. Therefore, the performance of the main task can be affected while increasing this fairness metric.

- **Equal Opportunity**: promotes that each group should get the positive outcome at equal rates, assuming there are reasons for individuals to belong to this subgroup. Different from Equalized odds, this metric accepts that different groups can have different output distributions and it is defined as:

$$P(\hat{Y} = 1 | A = 0, Y = 1) = P(\hat{Y} = 1 | A = 1, Y = 1).$$ (10)

The main drawback when using this metric to evaluate the learned model is obtaining a high rate of false positives. In this case, the overall model accuracy decreases, affecting the performance of the main task. A clear example of this case is the gender and racial gap in facial recognition performance [166]. If we optimize the current model for equalized odds, the overall face recognition performance will decrease.

- **Predictive Quality Parity**: is also called predictive rate parity and allows determining if the quality or precision rates are equivalent throughout different groups [167]. The quality is measured as the performance of the learned model by comparing predictions and groundtruth. We can use metrics such as accuracy, precision, recall, or F1 to obtain the quality rate, depending on the task. In robotics, for example, this metric is satisfied if the quality of the robot’s actions is the same for different genders.
it is also important to collect a representative sample in a dataset that accurately depicts the general population. Data disparity is the case where some groups are more represented than others in the dataset. Training a model with data disparity leads to optimization for the more represented groups to increase the general model performance, leading to poor prediction accuracy for the less represented group. In general, the data used for robot learning is sensitive to historical human biases and incomplete or unrepresentative training data, as illustrated in Fig. 4.

There are some works that include fairness-sensitive features in robot learning algorithms. For example, [184] uses a gender-specific behavior for navigation. Subsequently, [37] analyzes the challenges of using these explicit features in terms of social implications. Most robot learning algorithms do not explicitly use the so-called “protected” attributes to train the model. For example, it is not common to use “age” as an attribute to learn navigation models. On the other hand, it is more common that the learned models rely on raw input data. Nevertheless, the absence of explicitly encoded attributes in the input does not protect the output against bias related to these attributes. Unwanted discrimination can result in high relations between features and the task goal. For instance, even if we do not use gender as input to train a navigation model from human demonstrations, the model may learn “notions” of gender from the implicit information in the data. On top of that, data disparity can occur even if we do not use protected attributes related to an underrepresented group. Since the learned model aims to fit the training data and any training data is prone to contain bias, the models are susceptible to replicating the biases in data. Furthermore, learning models can also amplify societal stereotypes by using associations that might result in accurate but unfair performance. Even though bias is not always designated as negative, it is unfair when there is no valid reason for different outputs. Therefore, in data-level bias, the model biased output results from bias in the input data. In the following sections, we present an overview of methods for the detection and mitigation of bias at the data level.

1) Data Bias Detection: Discrimination in data can arise from the content of the data that reflects human biases and due to incomplete or unrepresentative information. In this direction, a previous work provides datasheets with a helpful protocol to follow when creating a dataset at the collection time [160]. On the other hand, in data bias detection, the goal is to analyze the data to find possible existing patterns of structural discrimination and the disproportion rate of samples of subgroups of people. For instance, as documented in [161], ImageNet [185], one of the most prominent vision datasets, contains demographic bias. To detect this bias, the authors performed a demographic annotation and analysis. Statistical analysis such as comparing label distribution regarding sensible attributes in the training data is a helpful tool for understanding discrimination in data.

2) Data Bias Mitigation - Preprocessing: The goal in data-level bias mitigation is to debias and improve the quality of the training dataset. Therefore, these bias mitigation approaches aim to refine the sample distributions of sensible attributes, filter samples that enforce bias or conduct data modification or augmentation to diminish discrimination due to the training data [186]. The main idea is to process the data to obtain a clean or restored version of the dataset for later use in the robot learning process [170]. A naive approach omits all the sensitive attributes so the model never uses them as input features and deletes the labels that generate the biased output. This approach is called Fairness Through Unawareness and assumes that by ignoring the sensible attributes, we can obtain a fair learned model [162]. The main limitation is that many highly correlated features might exist that are representative of sensitive attributes.

Unwanted outputs and discrimination towards diverse people in robot learning models are potentially provoked by the difference of label distribution in the training data. This unbalanced data is likely to significantly affect the most unrepresented individuals. To alleviate this representation bias, we aim to generate a balanced training dataset to increase the prediction quality of underrepresented groups by enforcing the dataset diversity. Therefore, datasets can be validated to understand if they contain potentially harmful biases or patterns that could lead to undesirable behavior. Different from the fairness context, [59] presents a framework to reduce dataset bias for grasping tasks. Their results show that current learning approaches can amplify biases in data, preventing the model from learning truly generalizable models. The authors highlight the importance of diversifying the data for robot learning. A similar approach can be defined to reduce bias towards fairness. For complex and risky tasks such as autonomous driving, the diversity of the data is a crucial element to learning generalizable models which can drive in all different environments around diverse individuals. Nevertheless, it is important to note that balanced datasets alone do not guarantee a solution for representation bias. Recent works demonstrate that even training a model with balanced data can lead to learned models that still recover in their intermediate representation attributes such as race and gender [187], [188].

Data filtering consists of removing the bias from the training data so that the model does not have to account for discrimination. Therefore, only fair examples are shown during training instead of using the available data, resulting in a fair model. The fairness motivated selection and sorting of data for robot learning remain unstudied. Nevertheless, the main idea of data filtering in the context of machine learning and artificial intelligence is that the downstream task can use the “cleaned” data representation and therefore produce results that preserve fair qualities. Fairness quality can be measured with metrics such as demographic parity, and individual fairness [143].
robotics, such a downstream task can be planning a navigation path for rescue or selecting a person to interact with. Therefore, these data filtering approaches in robotics aim to remove information from the dataset that might result in unfair decisions while trying to modify the original dataset as little as possible. As a result, the primary robot task performance is not affected during the learning process.

Consequently, for a biased dataset $D$, a repaired and cleaned dataset $\hat{D}$ is constructed which ignores the original bias-related information but is still as similar as possible to the original data $D$. In this direction, [171] presents a selection process for training data that improves the data quality in terms of ethical assessments of behavior and influences the training of the model. In their work, they present different use cases; one such case is self-driving cars. In terms of discrimination, the author states that biases are acceptable if they are critical for the legitimate solution of a given task. So the author proposes to promote biases in datasets used to train machine learning models that lead to a preference of desirable features from an ethical point of view. Similarly, [172] presents a solution to obtain a fairer subset of the samples. The authors find that cleaning the data helps make model predictions fair by balancing the true positive rate for the protected class across groups while maintaining the model’s overall performance. We can expect similar results in robotics. Nevertheless, for robot learning, data filtering is particularly challenging given that not only the training data is filtered but also in the final deployed system. Deploying robots in real-world environments implies that the robot encounters novel situations that can present biased data not considered to filter. Additionally, removing prejudices from the dataset or information that disproportionately favors or disfavors specific groups of people is a very challenging task, given that these aspects are difficult to identify.

Data augmentation refers to the process of creating new data samples using the information available in the training dataset. This process can increase the robustness of a model and prevent the model from overfitting. In this case, it is possible to replace fairness-sensitive features with alternative values that generate synthetic data to make the dataset more balanced where features and labels are edited to ensure group fairness [173]. In this direction, [174] propose to use data augmentation for reducing the negative effects of dataset bias for person re-identification. Nevertheless, research in this area still needs exploration.

The previous solutions for data-level bias mitigation present an additional challenge given that they rely on demographic labels annotation. In robotics, many datasets do not contain labels for sensible attributes. What is more, obtaining such annotations in many robotic tasks is highly expensive and sometimes impossible. In this case, unsupervised methods such as clustering can be used [37].

C. Model-Level Bias

In many robot learning scenarios, detecting bias in the input data is challenging. For instance, if we use human demonstrations of navigation trajectories to learn robot navigation, the resulting model can encode the gender attribute. The unwanted attribute encoding is prone to emerge in the model even if humans can not differentiate a feature such as gender, solely from trajectory data. With the resulting model, the robot might make decisions based on the implicitly learned attributes and produce unfair outcomes. Different factors such as redundant encodings or design choices during the robot learning process can lead to the model containing over associations between specific robot actions and protected attributes. Therefore, a model that relies on fairness-sensitive features is susceptible to cause discrimination. As a result, the learned model itself is leaned to retain encoded biased representations.

Formally, in model-level bias, the learned representation captures a bias-related attribute, and this attribute later contributes to the model prediction. This bias also prevents the model from learning richer representations since it incorrectly limits the optimization towards unwanted input-output associations. For example, a robot vision system that learns to identify pedestrians and relies on detecting specific skin colors [41]. In such cases, it is ideal that the prediction outcome discrimination is detected and removed from the model perspective. Approaches to mitigate model-level bias are divided into in-processing and post-processing. These approaches recognize that modeling techniques can lead to biased outputs by dominant features, distributional effects, or aim to produce accurate and fair models by finding a balance between accuracy and fairness model objectives. Moreover, model-level techniques tackle situations in which novel scenarios or situations appear, and it is necessary to adapt the learned model. These approaches tackle this challenging problem by often incorporating one or more fairness metrics into the model optimization function. Therefore, the goal is to maximize both performance and fairness notions.

1) Model Bias Detection: It is possible to detect bias in the model by measuring quality disparity. Biased models produce an imbalance in quality performance when comparing groups or individuals. The quality disparity is generally measured with a two-step method in the model learning process. First, the data is segmented into subgroups according to sensitive attributes. Second, we calculate and compare the accuracy for each subset. Different from quality disparity, model interpretation is also proposed as a discrimination debugging tool that analyzes the learned representations [168]. With model interpretation, their work aims to identify if a protected feature is encoded by the intermediate representation of a deep learning model and how the feature contributes to the model prediction. The reasons for discrimination are represented as class activation maps later used to investigate the models’ regions of interest when making decisions. The activation maps visualization is then used as a tool for interpreting the model. For instance, in their work, they present an example in face recognition where the model focuses on the eye region for lighter skin groups while focusing on the nose region and chin region for darker skin groups. Nevertheless, model bias detection in robot learning is still unexplored.

More specific in robot learning, [37] proposes to create a dataset with the robot experiences after deployment. Then this dataset can use clustering to analyze if the experiences are grouped and correlated to protected attributes. This is similar to the quality disparity but is achieved in an unsupervised manner. Additionally, [42] provides an analysis of pedestrian
Another possible approach consists of providing the robot with social skills. Inverse Reinforcement Learning is a technique used to train a robot model by learning a policy directly from human demonstrations in order to generate actions similar to human-like behavior. To include the social context in the learning process, these models aim to clone the behavior of humans. Subsequently, robots are then equipped with these models for socially-compliant actions [175], [176]. This approach has the potential for fairness-aware robot learning if we can guarantee that the demonstrations are bias-free. Nevertheless, this is a complex task that will also require the robot to learn only from a controlled and curated environment.

A different learning approach promising to diminish bias in the model is transfer learning. This approach aims to pretrain a robot model using a source domain dataset. This source dataset is rich with data from a group of people underrepresented in the primary dataset. Then, the pretrained model is transferred to the primary dataset, and the learning process continues as fine-tuning. Transfer learning can improve the general performance accuracy, as well as the performance accuracy for the underrepresented [179].

Process-based explainability is another promising approach for fairness-aware robot learning. Explainability is a challenging task in learning systems that consist of providing information that can clarify the input to output relationships. It is an essential step towards transparency in robotics. In general, for robot learning, we want explainability to include perception, decision, and action data to inform the reasoning behind the robot’s behavior. Ideally, this allows reconstructing an event or accident and highlighting changes to prevent unwanted robot actions. For fairness, the explanation can trace the design and the implementation elements to ensure fairness [194].

In the model-level training, adversarial approaches are also a possible solution to learn the main task without relying on information about sensitive attributes [180], [181] presents an approach for deep learning models where both predictor and classifier are learned together. In this case, the predictor is trained to learn the main prediction task, while the classifier penalizes the learned representation if the considered sensible attribute is predictable. However, more research is needed to apply this approach in the context of robot learning.

3) Model Bias Mitigation - Post-processing: Adaptability is an important attribute for robots to operate in the world. This allows the robots to appropriately function across diverse characteristics of specific users in the social environment where it is deployed. Therefore, in robot learning, post-processing approaches are critical. In this case, we recognize that the learned model may be unfair even if we include bias mitigation approaches in the data and model learning. Therefore, post-processing approaches update or transform the model to improve it in terms of fairness. This process is also called calibration or relearning [37], and its goal is to amend bias during the inference time. Therefore we can enforce prediction distribution to approach either the training distribution or a specific fairness metric. These methods allow for diverse fairness metrics and prove effective in reducing discrimination.

The learning-relearning approach [37] aims to include social and fairness notions into the different learning stages for robot navigation. Therefore, in this framework, socially-aware...
robot navigation requires planning motions according to social norms and socially compliant behavior. A fairness point of view in this context refers to promoting social good and avoiding prejudice through awareness and respect for human differences and necessities. Learning incorporates social context into learning navigation strategies so that robots can navigate in a socially compliant manner. Relearning diminishes any bias in the planned paths with the learned navigation model. The learning component can be obtained through Inverse Reinforcement Learning which allows capturing the navigation behavior of pedestrians. Then, for relearning, a reward or punishment system in an off-policy reinforcement learning algorithm optimizes an augmented reward that encodes the detection of unfair behavior.

Additionally, social adaptability is also a potential factor related to fairness. In this case, we aim that robots operate with human-like behavior. One such approach for robot navigation is proposed by [169]. It uses predicted human trajectories and a social cost function to plan collision-free paths that take human comfort into account. Additionally, their work uses time-dependent kinodynamic path planning to take into account the motion of the pedestrians around. In their work, the robot changes its navigation behavior to adapt to unforeseen changes in the environment. This principle can be projected into fairness motivation. Their work also highlights the relevance of testing in the real world to learn adaptability in social skills. Similarly, for fairness adaptability, real-world experiments are crucial before deployment.

V. PRACTICES FOR FAIR ROBOT LEARNING

We should account for humans’ safety, comfort, and non-discrimination while developing reliable robots that learn models to manipulate objects, navigate in social environments, and interact with humans. Besides exploring the social context, considerations, and implications, analyzing the legal framework, and defining and incorporating technical strategies, different practices are also helpful to ensure fairness in robot learning. Having guidelines for these practices aims to take care of details such as team creation, evaluation, and protocols of action in case of encountering unfair outputs in the learned model. Therefore in the following, we provide some initial practices for fairness-aware robot learning.

- Human-centered design: robot learning solutions involving the human perspective in all stages.
- Interdisciplinary perspectives: for robot learning development and evaluation.
- Explicit guidelines and policies for inclusion and non-discrimination: to increase diversity in work teams to provide integral solutions. Ideally, interdisciplinary and intercultural research groups will include different social perspectives to create empathetic solutions.
- Optimization techniques: different from optimization for efficiency and efficacy, explore approaches including constraints for optimization towards responsible robotics. Methods for ethical decision making.
- Early detection and correcting unwanted robot behavior: explore robot learning frameworks that penalize unwanted robot behavior and testing environments with novel metrics.
- Online evaluation to supervise models for responsible robotics: aim for models with adaptability skills. Include constant evaluation that includes new possible scenarios.
- Informed consequences and impact of the developments: to clarify the social impact and possible reach of the development.
- Conscious development: since robots can physically interact with humans, this implies that they can also physically harm them. It is essential to keep this in mind throughout the development.

VI. CONCLUSION

In this survey, we exposed potential adverse issues that can affect robot learning systems due to bias and unfairness in the learning algorithms. We demonstrated the extent to which such problems can affect our society through examples of real-world scenarios. By analyzing the challenges and defining the problem from three perspectives, we presented the technical, ethical, and legal advances made towards addressing fairness in machine learning for robotics. From the social focus, we created a taxonomy for different biases and categorized the resulting discrimination that can occur. We reviewed the legal and fairness considerations from an ethical and regulatory perspective. Inspired by recent advances in fair machine learning, we presented techniques for bias detection and mitigation in robot learning algorithms. We showed that the model bias to some extent exposes biases present in our society and robot learning algorithms should reduce these biases instead of amplifying them. The goal of this survey was to combine perspectives from different disciplines and provide tools, guidelines, and techniques towards fair robot learning that will eliminate disparity and promote fairness in the field.

ACKNOWLEDGEMENTS

This work was funded by the Carl Zeiss Foundation under the ReScalE project and a scholarship from the Graduate School of Robotics of the University Freiburg (according to the Graduate Funding Law of the Ministry of Science, Research and Arts of the State of Baden-Wurttemberg).

REFERENCES

Laura Londoño is a M.A. Student in Philosophy and a Assistant Research in the Robot Learning Lab at the University of Freiburg. She received her B.A. in Philosophy and Literature from the University of Caldas. Her research focuses on fair robotics, human-robot interaction, practical ethics and robotphilosophy.

Juana Valeria Hurtado is a Ph.D. Student in the Robot Learning Lab at the University of Freiburg, and is a scholarship holder in the Graduate School of Robotics. Her research focuses on learning-based methodologies for scene understanding and human-robot interaction with technical and social approaches. With her interests in robot learning and fairness, her aim is to equip robots with the abilities to operate in social environments while meeting performance, safety, and fairness criteria.

Nora Hertz is a Ph.D. candidate and research assistant at the Institute of Public Law Department 2 (Public International Law, Comparative Law, and Ethics of Law - Prof. Dr. Silja Vöneky) at the University of Freiburg. She studied law at Humboldt-University Berlin, Paris-Panthéon-Assas University and King’s College London (LL.M.). Her research focuses on human rights and neurotechnologies, particularly the right to freedom of thought and the right to private live, as well as human rights-based technology regulation.

Philipp Kellmeyer is a neurologist and neuroscientist at the Department of Neurosurgery of the University Medical Center Freiburg. In his neuroscience research, he works on speech and language processing in the brain and the application of digital technologies for neurological treatment and rehabilitation. He also heads the Neuroethics and AI Ethics Lab and co-leads the Responsible AI research focus where he works on participatory ethics-by-design approaches to responsible human-machine interactions in medicine.
Silja Voeneky is a full Professor of Public International Law, Comparative Law, and Ethics of Law and former Vice Dean of the Law Faculty at the University of Freiburg. She was a Fellow at Harvard Law School (2015–2016) and a Fellow at the 2018–2021 FRIAS Saltus Research Group “Responsible AI - Emerging ethical, legal, philosophical and social aspects of the interaction between humans and autonomous intelligent systems”. Her areas of research include laws of war, environmental law, human rights law, and the interdependence of Ethics and Law, esp. questions on the Governance of disruptive science and technologies. She previously served as Director of an Independent Max Planck Research Group (Heidelberg 2005–2010), and a member of the German Ethics Council appointed by the Federal Government. Since 2001, Voeneky has been a legal advisor to the German Federal Foreign Office, the German Federal Ministry of Research, and the German Federal Ministry of Environment.

Abhinav Valada is an Assistant Professor and Director of the Robot Learning Lab at the University of Freiburg. He is a member of the Department of Computer Science, a principal investigator at the BrainLinks-BrainTools Center, and a founding faculty of the European Laboratory for Learning and Intelligent Systems (ELLIS) unit at Freiburg. He received his Ph.D. in Computer Science from the University of Freiburg in 2019 and his M.S. degree in Robotics from Carnegie Mellon University in 2013. His research lies at the intersection of robotics, machine learning and computer vision with a focus on tackling fundamental robot perception, state estimation and control problems using learning approaches in order to enable robots to reliably operate in complex and diverse domains. Abhinav Valada is a Scholar of the ELLIS Society, a DFG Emmy Noether Fellow, and co-chair of the IEEE RAS TC on Robot Learning.
