Abstract

Molecular representation learning (MRL) is a key step to build the connection between machine learning and chemical science. In particular, it encodes molecules as numerical vectors preserving the molecular structures and features, on top of which the downstream tasks (e.g., property prediction) can be performed. Recently, MRL has achieved considerable progress, especially in deep molecular graph learning-based methods. In this survey, we systematically review these graph-based molecular representation techniques. Specifically, we first introduce the data and features of the 2D and 3D graph molecular datasets. Then we summarize the methods specially designed for MRL and categorize them into four strategies. Furthermore, we discuss some typical chemical applications supported by MRL. To facilitate studies in this fast-developing area, we also list the benchmarks and commonly used datasets in the paper. Finally, we share our thoughts on future research directions.

1 Introduction

The interaction between machine learning and chemical science has received great attention from researchers in both areas. It has made remarkable progress in various chemical applications including molecular property prediction \cite{Guo et al., 2020; Sun et al., 2021; Yang et al., 2021b; Liu et al., 2022b}, reaction prediction \cite{Jin et al., 2017; Do et al., 2019}, molecular graph generation \cite{Jin et al., 2018a; Jin et al., 2020b} and also drug-drug interaction prediction \cite{Lin et al., 2019}. Molecular representation learning (MRL) is an important step in bridging the gap between these two fields. MRL aims to utilize deep learning models to encode the input molecules as numerical vectors, which preserve useful information about the molecules and serve as feature vectors for downstream (machine learning) applications. Earlier molecular representation learning methods use general representation learning models to represent molecules without explicit involvement of domain knowledge. Recently, many algorithms are specifically designed for MRL, which can better incorporate chemical domain knowledge. In this paper, we provide a systematic review of the progress in this rapidly-developing topic, charting the path from representation learning methods that incorporate molecular structures to the methods that also incorporate domain knowledge.

Motivation 1: why molecular representation learning matters?

Molecular representation learning has a broad spectrum of applications closely related to people’s life. For example, drug discovery via wet-lab experimentation is extremely time-consuming and expensive. With the advancement of deep learning, a great number of experiments can be simulated by machine learning models. Property prediction can help identify the molecules with target properties. Reaction prediction could predict the major products. These significantly reduce the amount of failed experiments. For all these chemical applications, MRL is the key determinant of the success of deep learning models.

Motivation 2: why deep graph learning for molecular representation learning?

Molecular graphs naturally describe molecules with rich structural and spatial information. Molecules are essentially atoms and bonds interconnecting atoms, which naturally lead themselves to graph representations. Compared with SMILES, a line-based representation (i.e., string) of molecules, molecular graphs provide richer information for MRL models to learn from. As a result, graph-based MRL models evolve much faster than sequence-based MRL models. Additionally, more and more general graph learning papers \cite{Gilmer et al., 2017; Hu* et al., 2020; You et al., 2020} employ molecular graph datasets to examine the performance of their algorithms as well.

Contributions. The main contributions of this work are summarized as follows:

\begin{itemize}
  \item We present a systematic review of the recent progress in graph-based MRL models based on various kinds of molecular inputs and summarize the strategies specifically designed for MRL.
  \item To encourage reproducible research on this topic, we summarize the representative benchmarks and commonly used datasets in various downstream applications.
  \item We discuss the limitations of 2D and 3D molecular graphs as input and share our thoughts on future research directions of MRL for giving references to the community.
\end{itemize}
2 Data Representations

Traditionally, researchers use fixed fingerprint feature extraction rules to identify important information about each molecule and feed this hand-crafted information to a linear classification/regression head for downstream tasks. This requires significant time to determine and calculate the most relevant features, and the designed features still cannot support all tasks. To avoid these efforts, most deep learning models are developed to learn the molecular features automatically. Two kinds of molecular representations are used as inputs: molecular graphs and sequences. Accordingly, graph-based and sequence-based models are developed to learn from different input molecular representations. The sequence representations, such as simplified molecular input line-entry system (SMILES) [Weininger et al., 1989] and SELF-referencing Embedded Strings (SELFIES) [Krenn et al., 2020] can be converted into molecular graphs, but this conversion involves a significant amount of domain knowledge. When we take sequence representations as input, this knowledge is not easy to aware of by sequence-based learning models. In contrast, the graph representations can naturally incorporate additional information in nodes and edges, which is easily leveraged by the rich suite of graph-based models (e.g., graph neural networks). Therefore, we will focus on the graph representation in this survey, as it is more commonly used nowadays. In this section, we will clarify the molecular graphs (without spatial information) and 3D molecular graphs representations, as shown in Figure 1(a). For each representation, we analyze its characteristics and discuss its usages and limitations when utilized in deep learning models.

2.1 Molecular Graph

A graph consists of nodes and edges interconnecting the nodes. Analogously, in a molecule, we may consider atoms as nodes and bonds as edges between the atoms. Thus, a molecule has a natural graph structure. This renders the molecular graph to be the most feasible input for deep learning models and leads to their extensive use. The most common form of molecular graphs is described by three matrices: the node feature matrix, edge feature matrix, and adjacency matrix. Molecules are usually saved as SMILES for convenience and converted to molecular graphs for computation using specific tools. For example, RDKit [Landrum, 2019] or heterogeneous networks [Shui and Karypis, 2020] can convert a SMILES string into a molecular graph with the feature and adjacency matrices. The commonly used features of nodes and edges are listed in Table 1. In this table, atom and bond types are mandatory features to be included, while other features are optional and they can be included on demand for different tasks [Tang et al., 2020]. Among these features, the atom’s chirality tag cannot be learned from the common 2D molecular graph representation without 3D geometric information. Other features are all learnable from both 2D and 3D structures. For the connection relationship, we consider each bond as a bidirectional edge, which means that a bond between atom A and B will result in two edges in the adjacency list: one from A to B, another from B to A. Given the above data, researchers can leverage homogeneous [Gilmer et al., 2017] or heterogeneous networks [Guo et al., 2021, Coley et al., 2019] to learn molecular representations.

The advantage of using molecular graphs as input is obvious: graph neural networks can be applied directly to learn molecular representations using their topological structures. However, the bonds in this kind of graph are determined by the distance between atoms, which neglects the spatial direction and torsion between atoms. This limits the knowledge that can be derived from the general molecular graph.
2.2 3D Molecular Graph

The 3D molecular graph provides the missing geometric information by explicitly encoding the spatial structure. It provides the atomic structure as a set of atoms together with their 3D coordinates, which involves more atoms’ information. As a result, this representation format has received increasing attention in MRL [Liu et al., 2022b]. Different from taking 2D molecular graphs as input, the techniques based on the 3D graphs take atoms as nodes but learn the atomic interactions as edges using graph neural networks. Under this setting, the atom features are spatial-invariant (e.g., atom types) while the coordinates provide relative positions between atoms. For example, the bonds can be determined by the distance between two atoms using their coordinates. To incorporate more complicated spatial relationships, spherical graph neural networks [Liu et al., 2022b] are designed to learn molecule structure from the 3D graphs.

3 Methodology

In this section, we start with the general graph neural networks for MRL. Then, we discuss methods designed specifically for this task and categorize these methods into four strategies. These specific methods incorporate chemistry-related information to strengthen molecular representations in different ways, which leads to better performance. The representative methods are listed in Table 2.

Formally, each molecule generally is considered as an undirected graph \( G = (\mathcal{V}, \mathcal{E}, X) \) with node features \( x_v \in X \) for \( v \in \mathcal{V} \) and edge features \( e_{uv} \in \mathcal{E} \) for \( (u, v) \in \mathcal{E} \) [Brockschmidt, 2020]. Here, nodes represent atoms and edges represent bonds. Generally, graph-based learning methods can fit into Message Passing Neural Networks (MPNN) [Gilmer et al., 2017] scheme. Therefore, we take MPNN as an example to illustrate the learning process, as shown in Figure 1(b). The forward pass consists of three operations: message passing, node update, and readout. During the message passing phase, node features are updated iteratively according to their neighbors in the graph for \( T \) times. We initialize the embedding of node \( v \) as \( h_0^v = x_v \). Formally, node hidden states at step \( t+1 \) are obtained based on messages \( m_{t+1}^v \), which are represented as:

\[
m_{t+1}^v = \sum_{u \in \mathcal{N}(v)} M_t(h_t^u, h_t^v, e_{uv}),
\]

\[
h_{t+1}^v = U_t(h_t^v, m_{t+1}^v),
\]

where \( M_t \) is the message function, \( U_t \) is node update function, \( \mathcal{N}(v) \) is the set of node \( v \)'s neighbors in the graph. After updating the node features \( T \) times, the readout function \( R \) computes the whole graph embedding vector as follows:

\[
y = R(h_T^v \mid v \in \mathcal{V}).
\]

Note that, \( R \) is invariant to the order of nodes so that the framework can be invariant to graph isomorphism. \( y \) is the representation for the molecule and passed to a fully connected layer to do downstream tasks. All functions \( M_t, U_t, \) and \( R \) are neural networks with the learned weights updated during the training process.

Besides MPNN, different variants of graph neural networks like GCN [Kipf and Welling, 2017], GIN [Xu et al., 2019], GAT [Veličković et al., 2018], GGNN [Li et al., 2016], and GraphSAGE [Hamilton et al., 2017] can also be used directly to learn molecular representations. These methods are widely utilized as the base encoder for molecular representation learning in various downstream tasks, such as reaction prediction [Coley et al., 2019], property prediction [Brockschmidt, 2020] and drug discovery [Jin et al., 2020]. Hu et al. [Hu* et al., 2020] conduct a comparative study on graph neural networks in property prediction and find that GIN usually achieves the best results. While these models are powerful in learning graph structures, chemical traits, and knowledge, the essence of molecules is largely neglected. Recently, various deep learning methods are designed specifically for molecules as well. These methods are categorized into four parts in Figure 1(c), which are elaborated as follows.

3.1 Molecular Structure-based Method

Graph-based MRL generally considers molecular graphs the same as other plain graphs. It only focuses on the topological structures but cares less about special substructures or properties contained in the molecular graphs. Recent research has seen a foray into self-supervised learning strategies [Jin et al., 2020a] that push the model to pay more attention to the graph structures. PreGNN [Hu* et al., 2020] utilizes context prediction and node/edge attribute masking two self-supervised strategies to pre-train GNN. Different from this general unsupervised design, GROVER [Rong et al., 2020] proposes molecular-specific self-supervised pre-training methods: contextual property prediction and graph-level motif prediction. MGSSL [Zhang et al., 2021] also designs a motif-based graph self-supervised strategy, which predicts the motif’s topology and label during the motif tree generation process. INFOGRAPH [Sun et al., 2020] trains the model by maximizing the mutual information between the representations of the entire graph and substructures of different granularity.

Contrastive learning is a common self-supervised learning strategy, which utilizes data augmentation to make models produce graph representations with better generalizability, transferability, and robustness. Three general graph augmentation methods are proposed by GraphCL [You et al., 2020], which can also be applied to molecule datasets. MoCL [Sun et al., 2021] proposes two molecular graph augmentation methods: one is replacing a valid substructure with a similar physical or a chemical property-related substructure. The other one is changing a few general carbon atoms. Molecular 2D and 3D graph representations are naturally two augmented views of molecules. Using this characteristic, GeomGCL [Li et al., 2022] and GRAPHMVP [Liu et al., 2022a] train the model with contrastive learning. Molecu-

3.2 Domain Knowledge-based Method

Combining deep learning and molecular science is vital for molecular representation learning. Involving chemical domain knowledge in the model design is an effective way to improve performance. Yang et al. [Yang et al., 2021b] propose a novel model, PhysChem, which is composed of a physicist network (PhysNet) and a chemist network (ChemNet). PhysNet learns molecular conformations and ChemNet learns Chemical properties using neural networks. By fusing physical and chemical information, PhysChem obtains desired performance on property prediction tasks. PARD [Wang et al., 2021] involves task information and proposes a property-aware embedding method. Wang et. al. [Wang et al., 2022] are inspired by the relation of equivalence between reactants and products in a chemical reaction. They propose, MolR, to preserve the equivalence relation in the embedding space, which means forcing the sum of reactant embeddings and the sum of product embeddings to be equal. MolR achieves SOTA performance in a variety of downstream tasks.

3.3 Spatial Learning-based Method

Molecular spatial information, especially geometric information, attracts wide attention and is involved more and more in the molecular representation learning process, especially when the model needs to learn forces or energy on atoms. DimeNet [Klicpera et al., 2019], GemNet [Klicpera et al., 2021a] and Directional MPNN [Klicpera et al., 2021b] propose directional message embeddings. Although they still take 2D molecular graphs as input, they consider not only the distances between atoms but also the spatial directions, which are calculated by atoms’ 2D coordinates. They use directional information by transforming messages based on the angle between atoms. Using spherical Bessel functions and spherical harmonics, distance and angle can be jointly presented effectively. In general, 2D graph emphasizes topological information, while 3D geometric graphs focus more on energy. GeomGCL [Li et al., 2022] calculates the definite geometric factors (angle and distance) and utilizes radial basis functions to obtain geometric embeddings. GRAPHMVP [Liu et al., 2022a] adopts 3D conformers and learn molecular representations via 3D GNN model. To complete the identification of 3D graph structures, SphereNet [Liu et al., 2021] designs a spherical message passing as a powerful scheme for 3D molecular learning.
3.4 Knowledge Graph-based Method

The knowledge graph is an effective strategy to involve molecular-structure-invariant but rich external knowledge in the model. Different from previous methods, KGNN [Lin et al., 2020] and MDNN [Lyu et al., 2021] explore the knowledge graph consisting of molecules as nodes and connection relationship between molecules as edges. In this way, molecular representations are learned by the knowledge graph structure instead of molecular structure. Fang et al. [Fang et al., 2022] construct a chemical element knowledge graph, which is formed by triples in the form of (chemical element, relation, attribute), such as (Gas, isStateOf, Cl). They propose to use this KG to produce augmented nodes and edges in molecules and utilize contrastive learning to maximize agreement between two views of molecular graphs.

4 Applications

Here, we present several representative applications and algorithms to explain how models are designed to deal with the specific applications based on MRL.

4.1 Property Prediction

Molecular property prediction plays a fundamental role in drug discovery to identify potential drug candidates with target properties. Generally, this task consists of two phases: a molecular encoder to generate a fixed-length molecular representation and a predictor. A predictor is utilized to predict whether the molecule has the target property or predict the reaction of molecules to the target property based on learned molecular representation. Property prediction results can reflect the quality of learned molecular representation directly. As a result, property prediction tasks achieve great researchers’ attention. More and more general graph learning papers [Hu* et al., 2020, Gilmer et al., 2017; Brockschmidt, 2020; You et al., 2020] employ molecular graph datasets and property prediction tasks to examine the performance of their algorithms. What’s more, molecular specifically designed deep learning methods for MRL are proposed and applied in this task first. MoLR [Wang et al., 2022] proposes a novel way to learn molecular representation by keeping equivalence relation of the molecule reaction in the embedding space, which is also applied in the property prediction task first. Besides, the insufficient available molecular dataset is a common problem existing in the chemistry field. Guo et al. [Guo et al., 2021] and Wang et al. [Wang et al., 2021] propose meta-learning methods to deal with this problem on property prediction.

4.2 Molecular Generation

The key challenge of drug discovery is to find target molecules with the target properties, which heavily relies on domain experts. The molecular generation is to automate this process. Two steps are necessary to complete this task: one is designing an encoder to represent molecules in a continuous manner, which is beneficial to optimize and predict property; the other is proposing a decoder to map the optimized space to a molecular graph with the optimized property. Due to SMILES is not designed to capture molecular similarity, molecular generation models operate on molecular graphs directly most time. To avoid invalid states [Jin et al., 2018a], most works generate the graphs substructure by substructure instead of node by node. JT-VAE [Jin et al., 2018a] and VJTN [Jin et al., 2018b] decompose the molecular graph into the junction tree first, based on substructures in the graph. Then they encode the tree using a neural network. Next, they reconstruct the junction tree and assemble nodes in the tree back to the original molecular graph. HierVAE [Jin et al., 2020b] generates molecular graphs hierarchically based on motifs. MoLeR [Maziarz et al., 2022] keeps scaffolds structure during the generative procedure and generates molecules relying on motifs. GraphAF [Shi et al., 2020] utilizes the flow model to generate the molecular graph. MoleculeChef [Bradshaw et al., 2019] is the model designed to generate synthesizable molecules. It generates reactant molecules first and then utilizes the molecular transformer [Schwaller et al., 2019] model to generate the target molecule.

4.3 Reaction Prediction

Reaction prediction and retrosynthesis prediction are fundamental problems in organic chemistry. Reaction prediction means utilizing reactants to predict reaction products. The process of retrosynthesis prediction is the opposite of reaction prediction. When taking SMILES as input, the reaction prediction task is taken as a translation task. When taking molecular graphs as input, there are two steps to do both for reaction prediction and retrosynthesis prediction. Like WLDN [Jin et al., 2017] and WLDN+ [Coley et al., 2019], the model needs to predict the reaction center first and then predict the potential products which is the major product. Different from previous work, MoLR [Wang et al., 2022] formulates the task of reaction prediction as a ranking problem. All the products in the test set are put in the candidate pool. MoLR ranks these candidate products based on the embedding learned from given reactant sets.

4.4 Drug-drug Interactions

Detecting drug-drug interaction (DDI) is an important task that can help clinicians make effective decisions and schedule appropriate therapy programs. Accurate DDI can not only help medication recommendations but also effectively identify potential adverse effects, which is critical for patients and society. AttSemiGAE [Ma et al., 2018] proposes to do DDI by measuring drug similarity with multiple types of drug features. SafeDrug [Yang et al., 2021a] designs global and local two modules to fully encode the connectivity and functionality of drug molecules to make DDI. Both KGNN [Lin et al., 2020] and MDNN [Lyu et al., 2021] build the drug knowledge graph to improve the accuracy of DDI.

5 Datasets and Benchmarks

We summarize representative molecular representation learning algorithms in Table 2. To conveniently access the empirical results, each paper is attached with code links if available. Corresponding tasks, encoding algorithms, methods, and training methods are also listed. Here, methods specify four methods we discussed in Section 3. For training methods, we include self-supervised learning, supervised learning,

6 Future Directions

Graph-based methods for MRL develop fast. Although MRL has achieved satisfactory results applied in various applications, there are still some challenges that remain to be solved. We list several future directions for reference.

6.1 Graph-based MRL with Spatial Learning

3D geometric information attracts great attention recently in graph-based MRL. There are several ways to encode 3D information. One is an equivariant graph neural network, like the graph-based MRL. There are several ways to encode 3D information which contributes a lot to existing in the chemistry field. 3D molecular structures can provide more geometric information which contributes a lot to model training. Molecular conformation generation [Xu et al., 2021] is one of the solutions for this problem, but it has not been widely researched. Besides, Guo et al. [Guo et al., 2021] and Wang et al. [Wang et al., 2021] propose meta-learning algorithms to deal with the few-shot molecule problems, which also appeals to some following work. Algorithms proposed to deal with insufficient data problems should be another important research direction.

6.3 Graph-based MRL with Insufficient Data

Insufficient molecules for training is a common problem existing in the chemistry field. 3D molecular structures can provide more geometric information which contributes a lot to MRL. However, determining 3D structures from experiments is challenging and costly. Existing available 3D molecule graphs are insufficient for the model training. Molecular conformation generation [Xu et al., 2021] is one of the solutions for this problem, but it has not been widely researched. Besides, Guo et al. [Guo et al., 2021] and Wang et al. [Wang et al., 2021] propose meta-learning algorithms to deal with the few-shot molecule problems, which also appeals to some following work. Algorithms proposed to deal with insufficient data problems should be another important research direction.

7 Conclusion

Molecular representation learning builds a strong and vital connection between machine learning and chemical science. In this work, we introduce the problem of graph-based molecular representation learning and provide a comprehensive overview of the recent progresses on this research topic. To facilitate reproducible research, we take the first step to release the representative molecular representation learning benchmarks and commonly used datasets for the research.
community. Finally, we share our thoughts about future directions in this topic.
