Transferability-Guided Cross-Domain Cross-Task Transfer Learning

Yang Tan, Yang Li, Shao-Lun Huang, Xiao-Ping Zhang, Fellow, IEEE

Abstract—We propose two novel transferability metrics F-OTCE (Fast Optimal Transport based Conditional Entropy) and JC-OTCE (Joint Correspondence OTCE) to evaluate how much the source model (task) can benefit the learning of the target task and to learn more transferable representations for cross-domain cross-task transfer learning. Unlike the existing metric that requires evaluating the empirical transferability on auxiliary tasks, our metrics are auxiliary-free such that they can be computed much more efficiently. Specifically, F-OTCE estimates transferability by first solving an Optimal Transport (OT) problem between source and target distributions, and then uses the optimal coupling to compute the Negative Conditional Entropy between source and target labels. It can also serve as a loss function to maximize the transferability of the source model before finetuning on the target task. Meanwhile, JC-OTCE improves the transferability robustness of F-OTCE by including label distances in the OT problem, though it may incur additional computation cost. Extensive experiments demonstrate that F-OTCE and JC-OTCE outperform state-of-the-art auxiliary-free computation cost. Extensive experiments demonstrate that F-OTCE and JC-OTCE outperform state-of-the-art auxiliary-free metrics by 18.85% and 28.88%, respectively in correlation coefficients with the ground-truth transfer accuracy. By eliminating the training cost of auxiliary tasks, the two metrics reduces the total computation time of the previous method from 43 minutes to 9.32s and 10.78s, respectively, for a pair of tasks. When used as a loss function, F-OTCE shows consistent improvements on the performance of the source model in few-shot classification experiments, with up to 4.41% accuracy gain.

Index Terms—Transfer learning, few-shot learning, transferability estimation, task relatedness, cross-domain, cross-task, source selection.

I. INTRODUCTION

Transfer learning is an effective learning paradigm to enhance the performance on target tasks via leveraging prior knowledge from the related source tasks (or source models), especially when there are only few labeled data for supervision [1], [2]. However, the success of transfer learning is not always guaranteed. If the source and target tasks are unrelated, or if the transferred representation does not carry sufficient information about the target task, transfer learning will not obtain a notable gain on the target task performance, and may even experience negative transfer, i.e., the performance becomes worse than that of training from scratch on the target task [3]. Therefore, understanding when and what to transfer between tasks is crucial to the success of transfer learning.

Fig. 1. Illustration of three different transfer learning settings, i.e., transductive domain adaptation [4], cross-task transfer [5] and the cross-domain cross-task transfer we investigating.

The “when to transfer” problem was traditionally studied theoretically through the derivation of generalization bounds of transfer learning across tasks [6], [7] and across domains (also known as the domain adaptation problem) [8]–[11]. Such studies bound the target task generalization error by a function that depends on certain divergence between the source and target domain, or the complexity of the hypothesis class for the source and target tasks. In practice, however, these bounds are difficult to compute from data and they tend to rely on strict assumptions that can not be verified. In recent years, the notion of task transferability was proposed to address the “when to transfer” problem in the context of deep transfer learning [5], [12]–[19]. The transferability problem aims to quantitatively evaluate how much the source task or source model could benefit the learning of the target task. It can be used to directly select the most “transferable” source model from a model zoo for a target task, rather than exhaustively trying each source model on the target data. In addition, transferability can help prioritize different tasks for joint training [12] and multi-source feature fusion [18].

As empirical transferability metrics [12]–[15] incur heavy computation burdens in retraining the transfer learning model on the target training data, a new trend of analytical transferability research aims to estimate the transfer performance a-priori with little or no training of the transfer model. Several analytical transferability metrics are proposed, including NCE [16], H-score [5], LEEP [17], and LogME [19]. Despite of being evidently more efficient to compute from practical data than empirical methods, they are also prone to strict data assumptions [5], [16] and insufficient performance [17], [19] while task complexities are similar. Moreover, the aforementioned metrics have only been used to characterize when to transfer between a pair of source and target tasks, but they do not contribute to solving the “what to transfer” problem, i.e.
how to find more transferable source representations across domains and tasks.

Recently, a novel transferability metric **OTCE** (Optimal Transport based Conditional Entropy) [18] is proposed to effectively estimate the transferability under the challenging cross-domain cross-task transfer setting, shown in Fig. 1. More concretely, the OTCE metric explicitly evaluates the domain difference (Wasserstein distance) and the task difference (conditional entropy) between tasks, and then combines them via a linear model for describing transferability. Such technically sound design indeed achieves significant accuracy gain compared to those metrics mentioned above. However, an inherent drawback of OTCE is relying on auxiliary tasks with known transfer performance to help determine the intrinsic parameters of the linear model. On the one hand, we are not always able to access sufficient target labeled data for constructing auxiliary tasks. On the other hand, obtaining the transfer performance of auxiliary tasks needs to retrain the source model, which is computationally expensive and time consuming. Therefore, the dependency on auxiliary tasks makes OTCE relatively inefficient and less applicable in practical scenarios.

In this paper, we propose two auxiliary-free transferability metrics, namely **F-OTCE** (Fast OTCE) and **JC-OTCE** (Joint Correspondence OTCE) that remove the requirement on auxiliary tasks and dramatically improve the efficiency without losing accuracy. For classification problems, the F-OTCE metric first solves the Optimal Transport (OT) problem [20], [21] for estimating a probabilistic coupling between the unpaired samples from the source and the target datasets. Then the optimal coupling allows us to derive the negative conditional entropy between the source and target task labels for representing transferability, which measures the label uncertainty of a target sample given the labels of those corresponding source samples. Although the F-OTCE metric does not explicitly evaluate the domain difference, the estimated probabilistic coupling between the source and target data already to some extent captures the domain difference implicitly in this unified framework.

Then we propose the JC-OTCE metric to further improve the robustness of the F-OTCE metric on some difficult cases. The motivation is that the F-OTCE metric does not involve the label information in computing the optimal coupling between data, making it not always precisely reveal the class-to-class matching quality through the built correspondences. As a result, we define a new ground cost in the OT problem containing both the sample distance and the label distance, so that the coupling results can be considered as computed from the joint space of the sample space and the label space. Thanks to incorporating the additional label information, JC-OTCE is more accurate than F-OTCE and it is comparable to the auxiliary-based OTCE metric in accuracy. Nevertheless, since JC-OTCE incurs additional computation cost to F-OTCE, the latter metric is still preferable when efficiency performance is prioritized.

For learning more transferable representations in neural network based transfer learning, we propose a transferability-guided transfer learning algorithm called **OTCE-based fine-tune** to directly learn the more transferable representations from the source and target data, offering a solution to the “what to transfer” problem. The basic idea is that by maximizing the transferability of the source model, we can obtain a better embedded data structure for the target task so that the target classifier can be easily learned. Specifically, given a pretrained source model and a target task, this algorithm first optimizes the source model via maximizing the F-OTCE score between the source task and the target task. It then finetunes the optimized model on target training data using the classification loss function.

The major contributions of this work are summarized as follows:

1) **Two auxiliary-free analytical transferability metrics.** We propose the F-OTCE and the JC-OTCE metrics which can accurately predict the transfer performance of the source model without the requirement of auxiliary tasks or any further training.

2) **A transferability-guided transfer learning method.** Using the F-OTCE metric as an optimization objective, we propose to optimize the source model via maximizing the transferability to obtain more transferable feature representations, leading to a higher transfer accuracy on the target task.

In our experiments using several multi-domain classification datasets, we show that our proposed two metrics significantly outperform state-of-the-art auxiliary-free metrics with 24% correlation gain on average, while cutting more than 99% of the computation time in the auxiliary-based OTCE. We also show that, when served as a loss function, F-OTCE leads to notable accuracy gains on few-shot classification tasks, with up to 4.41%. The rest of this paper is organized as follows. Section II introduces the formulation of transferability. Section III presents our two auxiliary-free transferability metrics. Section IV illustrates our OTCE-based finetune algorithm. Section V provides all the experimental results and analyses. Finally, we draw the conclusion in Section VI.

**II. Transferability Formulation**

Here we introduce the formal definition of transferability. Suppose we have source data \( D_s = \{(x_s^i, y_s^i)\}_{i=1}^m \sim P_s(x, y) \) and target data \( D_t = \{(x_t^i, y_t^i)\}_{i=1}^n \sim P_t(x, y) \), where \( x \) represents the input instance and \( y \) denotes the label. We have \( x_s^i, x_t^i \) from the input space \( \mathcal{X} \), and \( y_s^i, y_t^i \) from the source label space \( \mathcal{Y}_s \), and \( y_t^i \) from the target label space \( \mathcal{Y}_t \). Meanwhile, \( P(x_s) \neq P(x_t) \) and \( \mathcal{Y}_s \neq \mathcal{Y}_t \) indicate different domains and tasks respectively. In addition, we are given a source model \((\theta_s, h_s)\) pretrained on source data \( D_s \), in which \( \theta_s : \mathcal{X} \rightarrow \mathbb{R}^d \) represents a feature extractor producing \( d \)-dimensional features and \( h_s : \mathbb{R}^d \rightarrow P(\mathcal{Y}_s) \) is the head classifier predicting the final probability distribution of labels, where \( P(\mathcal{Y}_s) \) is the space of all probability distributions over \( \mathcal{Y}_s \). Note that the notation \( \theta \) and \( h \) can also represent model parameters.

In this paper, we mainly investigate the transferability estimation problem with two representative transfer paradigms for neural networks [3], i.e., **Retrain head and Finetune**. The **Retrain head** method keeps the parameters of the source feature extractor \( \theta_s \) frozen and re trains a new head classifier \( h_t \). But the **Finetune** method updates the source feature
extractor and the head classifier simultaneously to obtain new \((\theta_i, h_i)\). Compared to Retrain head, Finetune trade-offs transfer efficiency for better transfer accuracy and it requires more target data to avoid overfitting [18].

To obtain the empirical transferability, we need to retrain the source model via Retrain head or Finetune on target data and then evaluate the expected log-likelihood on its testing set. Formally, the empirical transferability is defined as:

**Definition 1:** The empirical transferability from the source task \(S\) to the target task \(T\) is measured by the expected log-likelihood of the retrained \((\theta_s, h_s)\) or \((\theta_t, h_t)\) on the testing set of target task:

\[
\text{Trf}(S \rightarrow T) = \left\{ \begin{array}{ll}
E[\log P(y_t|x_t;\theta_s, h_s)] & \text{(Retrain head)} \\
E[\log P(y_t|x_t;\theta_t, h_t)] & \text{(Finetune)}
\end{array} \right.,
\]

which indicates how good the transfer performance is on the target task. In practice, we usually take the testing accuracy as an approximation of the log-likelihood [16], [18].

Although the empirical transferability can be the golden standard of describing how easy it is to transfer the knowledge learned from a source task to a target task, it is computationally expensive to obtain. Analytical transferability metric is a function of the source and target data that efficiently approximates the empirical transferability, i.e., the ground-truth of the transfer performance on target tasks. It is therefore imperative to find efficient analytical transferability metrics that can accurately estimate empirical transferability.

### III. Auxiliary-free Transferability Metrics

Our proposed auxiliary-free transferability metrics **F-OTCE (Fast OTCE)** and **JC-OTCE (Joint Correspondence OTCE)** can be considered as the efficient implementations of the auxiliary-based OTCE metric, where we only take the Negative Conditional Entropy for describing transferability, as shown in Fig. 2. Although we do not explicitly evaluate the domain difference, the estimated probabilistic coupling between the source and target data already to some extent captures the domain difference implicitly in this unified framework.

Specifically, F-OTCE offers better efficiency, while JC-OTCE offers better robustness under larger joint distribution shifts. The main difference between the two metrics is that the ground cost of JC-OTCE in calculating the optimal coupling between the source and target data already considers both the sample distance and label distance, which is an approximation of computing ground cost in the joint space \(X \times Y\).

#### A. F-OTCE Metric

Formally, we first use the source feature extractor \(\theta_s\) to embed the source and target input instances as latent features, denoted as \(\tilde{x}_s = \theta_s(x_s^i)\) and \(\tilde{x}_t = \theta_t(x_t^j)\) respectively. Then the computation process contains two steps as described below.

**Step1: Compute optimal coupling.** First, for the F-OTCE metric, we define the ground cost between samples as:

\[
c_1(\tilde{x}_s^i, \tilde{x}_t^j) \triangleq \|\tilde{x}_s^i - \tilde{x}_t^j\|^2_2, \tag{2}
\]

**Step2: Compute F-OTCE.** Then the F-OTCE is defined as:

\[
\lambda_1 \|\tilde{x}_s - \tilde{x}_t\|^2_2 + \lambda_2 \|\tilde{x}_t - \tilde{x}_s\|^2_2 + b.
\]

Fig. 2. Illustration of the auxiliary-based OTCE metric [18] (top), and our proposed F-OTCE (middle) and JC-OTCE (bottom) metrics which do not require auxiliary tasks with known transfer accuracy to learn the weighting coefficients. For OTCE (top), \(W_D\) and \(W_T\) represent the domain difference and task difference between two tasks, respectively. To estimate the coefficients \(\lambda_1, \lambda_2, b\) of the linear model, we need to sample at least three auxiliary tasks from the target dataset and calculate \(W_D^i, W_T^j\) and transfer accuracy \(\text{TransferAcc}^i_j\) between the source task and each auxiliary task as training data.

**Definition 2:** Formally, we first use the source feature extractor \(\theta_s\) to embed the source and target input instances as latent features, denoted as \(\tilde{x}_s = \theta_s(x_s^i)\) and \(\tilde{x}_t = \theta_t(x_t^j)\) respectively. Then the computation process contains two steps as described below.

**Step1: Compute optimal coupling.** First, for the F-OTCE metric, we define the ground cost between samples as:

\[
c_1(\tilde{x}_s^i, \tilde{x}_t^j) \triangleq \|\tilde{x}_s^i - \tilde{x}_t^j\|^2_2, \tag{2}
\]

**Step2: Compute F-OTCE.** Then the F-OTCE is defined as:

\[
\lambda_1 \|\tilde{x}_s - \tilde{x}_t\|^2_2 + \lambda_2 \|\tilde{x}_t - \tilde{x}_s\|^2_2 + b.
\]
so the OT problem with the entropic regularization [22] can be defined as:

$$OT(X_s, X_t) \triangleq \min_{\pi \in \mathcal{P}(X_s, X_t)} \sum_{i,j=1}^{m,n} c_{ij}(\tilde{x}_s^i, \tilde{x}_t^j)\pi_{ij} - \lambda H(\pi), \quad (3)$$

where $\pi$ is the coupling matrix of size $m \times n$, and $H(\pi) = -\sum_{i=1}^{m} \pi_{ij} \log \pi_{ij}$ is the entropic regularizer with $\lambda = 0.1$. The OT problem above can be solved efficiently by the Sinkhorn algorithm [22] to produce an optimal coupling matrix $\pi^*$.

From a probabilistic point of view, the coupling matrix $\pi^*$ is a non-parametric estimation of the joint probability distribution of the source and target latent features $P(X_s, X_t)$.

We model the relationship between the source and the target data according to the following simple Markov random field: $Y_s - X_s - X_t - Y_t$, where label random variables $Y_s$ and $Y_t$ are only dependent on $X_s$ and $X_t$, respectively, i.e., $P(Y_s, Y_t | X_s, X_t) = P(Y_s | X_s) P(Y_t | X_t)$. Furthermore, we can derive the empirical joint probability distribution of the source and target labels,

$$P(Y_s, Y_t) = \mathbb{E}_{X_s, X_t}[P(Y_s | X_s) P(Y_t | X_t)]. \quad (4)$$

This joint probability distribution can reveal the transfer performance, since the goodness of class-to-class matching intuitively reveals the hardness of transfer.

**Step2: Compute negative conditional entropy.** We are inspired by Tran et al. [16] who use Conditional Entropy (CE) $H(Y_s | Y_t)$ to describe class-to-class matching quality over the same input instances. They have shown that the empirical transferability is lower bounded by the negative conditional entropy,

$$\hat{\text{Trf}}(S \rightarrow T) \geq l_S(\theta_s, h_s) - H(Y_s | Y_t), \quad (5)$$

where the training log-likelihood $\hat{\text{Trf}}(S \rightarrow T) = l_T(\theta_s, h_t) = \frac{1}{n} \sum_{i=1}^{n} \log P(y_t^i | x_t^i; \theta_s, h_t)$ is an approximation of the empirical transferability when the retrained model is not overfitted. And $l_S(\theta_s, h_s)$ is a constant, so the empirical transferability can be attributed to the conditional entropy.

We consider it as a reasonable metric to evaluate transferability under the cross-domain cross-task transfer setting once we learn the soft correspondence $\pi^*$ between source and target features via optimal transport. We can also compute the empirical joint probability distribution of the source and target labels, and the marginal probability distribution of the source label, denoted as:

$$\hat{P}(y_s, y_t) = \sum_{i,j: y_s^i = y_t^j} \pi_{ij}^*, \quad (6)$$

$$\hat{P}(y_s) = \sum_{y_t \in Y_t} \hat{P}(y_s, y_t). \quad (7)$$

Then we can compute the negative conditional entropy as the F-OTCE score,

$$\text{F-OTCE} = -H_{\pi^*}(Y_t | Y_s) = \sum_{y_s \in Y_s} \sum_{y_t \in Y_t} \hat{P}(y_s, y_t) \log \frac{\hat{P}(y_s, y_t)}{\hat{P}(y_s)}, \quad (8)$$

**Fig. 3.** A toy example shows that the F-OTCE metric fails to distinguish the more transferable source model, while the JC-OTCE predicts correctly with involving the label distance in computing the correspondences.

Compared to the auxiliary-based OTCE, we directly use the negative conditional entropy to characterize transferability, which avoids the cumbersome parameter fitting process on auxiliary tasks, resulting in a drastic efficiency improvement.

**B. JC-OTCE Metric**

F-OTCE is an effective transferability metric in practical scenarios, but it can be further improved while encountering some difficult cases. Take a toy example shown in Fig. 3 for illustration, where the F-OTCE metric fails to distinguish the more transferable source model. It inspires us that computing the correspondences based on the sample distance (in space $X$) alone may not always precisely capture the class-to-class matching quality (or the label uncertainty of the target task) as expected. Therefore, to further improve the robustness of F-OTCE, we propose the JC-OTCE metric which involves the additional label distance in computing the joint correspondences between data in the joint space $X \times Y$.

Formally, we first define the data instances of the source and target tasks as $z_s = (x_s, y_s)$ and $z_t = (x_t, y_t)$ respectively, where $z_s \in Z_s = X \times Y_s$ and $z_t \in Z_t = X \times Y_t$. And we define the $\alpha_y \triangleq P(X | Y = y)$, which can be estimated from a collection of finite samples with label $y$. Inspired by recent work [23], we compute the label distance as the Wasserstein distance $\text{Wass}(\alpha_{y_s}, \alpha_{y_t})$. Then the ground cost for JC-OTCE can be defined as:

$$c_z(x_s^i, z_t^j) \triangleq \gamma \|x_s^i - x_t^j\|_2^2 + (1 - \gamma)\text{Wass}(\alpha_{y_s^i}, \alpha_{y_t^j}), \quad (9)$$

where $\gamma \in [0, 1]$ is a weighting coefficient to combine the sample distance and the label distance, and here we let $\gamma = 0.5$. More discussion about $\gamma$ is described in Section V-C. Similarly, the OT problem for $Z_s$ and $Z_t$ is defined as:

$$OT(Z_s, Z_t) \triangleq \min_{\pi \in \mathcal{P}(Z_s, Z_t)} \sum_{i,j=1}^{m,n} c_z(z_s^i, z_t^j)\pi_{ij} - \lambda H(\pi). \quad (10)$$

By solving this OT problem, we also obtain the optimal coupling matrix $\pi^*$. Then following the **Step2** described in
previous Section III-A (see Equation (6), (7)), the JC-OTCE score is computed as the negative conditional entropy as well.

\[
\text{JC-OTCE} = -H_{\pi^*}(Y_t|Y_s) = \sum_{y_t \in Y_t} \sum_{y_s \in Y_s} \hat{P}(y_s, y_t) \log \frac{\hat{P}(y_s, y_t)}{\hat{P}(y_s)}. \tag{11}
\]

IV. TRANSFERABILITY-GUIDED TRANSFER LEARNING

We further propose a transferability-guided transfer learning method named \textbf{OTCE-based finetune} that learns a modified source model \(\hat{\theta}_s\) by directly maximizing the model’s transferability to the target task. The classic finetuning approach assumes that target samples evaluated on the source model \(\theta_s(x_t)\) have a nice structure with respect to target labels \(y_t\), such that the target classifier \(h_t\) can be easily learned. When the transferability of the original source model is low, such assumptions cannot be established and simply finetuning would lead to overfitting. To ease this problem, our OTCE-based finetune algorithm optimizes the source model to be more transferable to the target task and ultimately achieve a higher transfer accuracy.

Here we take the F-OTCE metric as the optimization objective to facilitate the training procedure, since the JC-OTCE metric needs to compute pair-wise label distances by solving multiple OT problems which cost much more computations. Meanwhile, JC-OTCE is difficult to be implemented as a differentiable loss function layer in deep neural networks.

We apply the OTCE-based finetune algorithm to the challenging cross-domain few-shot classification problem, since it is a very practical scenario where the transfer learning can effectively benefit the model training from few labeled target data.

A. Few-shot Classification Task Definition

For the cross-domain few-shot classification problem, we have three datasets: a source dataset, a target support (training) set, a target query (testing) set. The label space of the source data is usually disjoint with the target data. We can train the source model on the source dataset via supervised learning, meta learning, etc. After obtaining the source model, we transfer the source model to the few-shot target task.

A few-shot classification task known as \textit{C-way-K-shot} means that the support set \(S = \{(x^i, y^i)\}_{i=1}^{k \times C}\) contains \(k\) labeled instances from each of the \(C\) categories. And the query set \(Q = \{(x^i, y^i)\}_{i=1}^{q \times C}\) containing \(q\) samples per category serves as the testing set to evaluate the performance of the model learned from the support set.

B. OTCE-based Finetune

As depicted in Fig. 4 and Algorithm 1, the OTCE-based finetune algorithm is a two-step framework. First, we optimize the source feature extractor \(\hat{\theta}_s\) via minimizing the conditional entropy within one epoch. Formally,

\[
\hat{\theta}_s^* = \arg \min_{\theta_s} H_{\pi^*}(Y_t|Y_s) = -\arg \min_{\theta_s} \sum_{y_t \in Y_t} \sum_{y_s \in Y_s} \hat{P}(y_s, y_t) \log \frac{\hat{P}(y_s, y_t)}{\hat{P}(y_s)}, \tag{12}
\]

where \(\pi^*\) is the optimal coupling matrix computed from Equation (3). Joint label distribution \(\hat{P}(y_s, y_t)\) and marginal \(\hat{P}(y_s)\) are computed from Equation (6), (7). The computation of solving the OT problem with entropic regularizer [22] (Equation (3)) is differentiable [24] since the iterations form a sequence of linear operations, so it can be implemented on the PyTorch framework as a specialized layer\(^1\) of the neural network. After that, we initialize the target feature extractor \(\theta_t\) from the optimized source weights \(\hat{\theta}_s^*\), and then retrain the target model \((\theta_t, h_t)\) on the target training data using the cross-entropy loss function,

\[
\theta_t^*, h_t^* = \arg \max_{\theta_t, h_t} \sum_{i=1}^{m} \sum_{l=1}^{k} \mathbb{1}(y^i_l = l) \log \frac{\exp(h_t^l(\theta_t(x^i_l)))}{\sum_{j=1}^{k} \exp(h_t^j(\theta_t(x^i_l)))}, \tag{13}
\]

where \(m\) represents the number of target training samples, and \(k\) is the number of the categories of the target task.

Note that we do not make it a one-step framework, i.e., simultaneously maximize the transferability and minimize the classification loss. Because optimizing two objectives simultaneously may cause gradient conflicts in mini-batch training, which will deteriorate the final classification performance.

V. EXPERIMENTS

In this part, we first quantitatively evaluate the performance of our proposed two auxiliary-free metrics on transferability estimation problems under various cross-domain cross-task transfer settings. In addition, more analyses on computation efficiency and hyper parameter are also introduced. Then we evaluate our proposed OTCE-based finetune algorithm on two cross-domain few-shot classification settings.

A. Evaluation on Transferability Estimation

Datasets. Our experiments are conducted on the data from the largest-to-date cross-domain dataset DomainNet [25] and popular Office31 [26] dataset. The DomainNet dataset contains 345-category images in five domains (image styles), i.e., Clipart (C), Painting (P), Quickdraw (Q), Real (R) and Sketch (S), and the Office31 contains 31-category images in three domains including Amazon (A), DSLR (D) and Webcam (W). Data examples are shown in Fig. 5.

Evaluation criteria. To quantitatively evaluate the effectiveness of transferability metrics, we adopt the commonly used Spearman’s rank correlation coefficient (Spearman’s ρ coefficient) and the Kendall rank correlation coefficient (Kendall’s τ coefficient) [27] to assess the correlation between the transfer accuracy and predicted transferability scores. Specifically, the Spearman’s ρ coefficient is defined as:

$$
ρ = 1 - \frac{6 \sum d_i^2}{n(n^2-1)},
$$

where \(d_i = R(\text{Acc}_i) - R(\text{Trf}_i)\) is the difference between the rankings of transfer accuracy \(\text{Acc}_i\) and transferability score \(\text{Trf}_i\) for the \(i\)th source-target task pair, and \(n\) represents the total number of task pairs.

The Kendall’s τ coefficient in our experiments is defined as:

$$
τ = \frac{2}{n(n-1)} \sum_{i<j} \text{sgn}(\text{Acc}_i - \text{Acc}_j)\text{sgn}(\text{Trf}_i - \text{Trf}_j).
$$

The Kendall’s τ coefficient computes the number of concordant pairs minus the number of discordant pairs divided by the number of total pairs. A higher rank correlation indicates the more accurate transferability estimation result.

Transfer settings. We successively take each domain as the source domain and use the rest as target domains. For each target domain, we generate 100 target tasks by randomly sampling images in different categories. Then we transfer the source models (ResNet-18 [28]) pretrained on all source domain data to each target task to obtain the ground-truth transfer accuracy. To investigate the performance of transferability metrics under various transfer configurations, three different transfer settings are considered, i.e., the standard setting, the few-shot setting, and the fixed category size setting.

1) standard setting. We keep all the training samples of the target task for retraining the source model. Meanwhile, the number of categories of target tasks ranges from 10 to 100 for DomainNet, and from 10 to 31 for Office31 respectively. Thus we totally conduct \(5 \times 4 \times 100 = 2000\) cross-domain cross-task transfer tests on DomainNet, and \(5 \times 2 \times 100 = 600\) tests on Office31.

2) few-shot setting. As transfer learning is commonly used in the scenario where only few labeled data are provided, it is worthy to evaluate the robustness of transferability metrics on few-shot cases. The only difference with the standard setting is that we allow the target tasks only have 10 training samples per category.

3) fixed category size setting. As studied in [18], the intrinsic complexity of the target task, e.g. category size (number of categories), also affects the transfer accuracy. Usually a larger category size makes the target task more difficult to learn from limited data. As a result, in previous two settings, the intrinsic complexity of target tasks with different category sizes may overshadow the more subtle variations in the relatedness with the source task. To investigate whether the transferability metrics are capable of capturing those subtle variations, we propose a more challenging fixed category size setting where all target tasks have the same category size = 50. Other configurations are same as the standard setting.

For all the settings above, we adopt a SGD optimizer with learning rate = 0.01 to optimize the cross-entropy loss for 100 epochs during the transfer training phase.

Results. Quantitative comparisons with state-of-the-art auxiliary-free transferability metrics including LEEP [17], NCE [16], H-score [5], LogME [19] are shown in Table I, and visual comparisons are illustrated in Fig. 6. Firstly, we can see that both our JC-OTCE and F-OTCE metrics consistently outperform recent LEEP, NCE, H-score and LogME metrics on all three transfer settings. In particular, our JC-OTCE metric achieves (5.5%, 10.3%, 22.3%, 37.3%) and (9.6%, 12.9%, 40.7%, 52.3%) average gains on Kendall correlation compared to LEEP, NCE, H-score and LogME respectively under the standard setting and the few-shot setting. Moreover, the H-score metric and the LogME metric failed under the more challenging fixed category size setting, where they showed a negative correlation with the transfer accuracy.

Secondly, the JC-OTCE metric outperforms the F-OTCE metric with an average 5.3% gain on Kendall correlation, which shows that involving the label distance in computing the data correspondences makes the transferability estimation more robust. Meanwhile, the JC-OTCE metric performs comparably to the auxiliary-based OTCE metric [18], while the former one is evidently more efficient and has less restrictions.

Basically, we can conclude that OTCE ≈ JC-OTCE ≈ F-OTCE.
### TABLE I
Quantitative comparisons evaluated by the Spearman’s $\rho$ coefficient and Kendall’s $\tau$ coefficient between transferability metrics and transfer accuracy under different cross-domain cross-task transfer settings for image classification tasks. Our proposed JC-OTCE and F-OTCE metrics consistently outperform state-of-the-art auxiliary-free metrics. Meanwhile, the JC-OTCE achieves comparable performance with the auxiliary-based OTCE.

F-OTCE on accuracy and OTCE < JC-OTCE < F-OTCE on efficiency. These three metrics can be applied flexibly according to the needs of different practical situations.

#### B. Efficiency Analysis

Given $d$-dimensional extracted features of $m$ source samples and $n$ target samples, assuming $|\mathcal{X}_s|, |\mathcal{X}_t| < \min(m, n)$, the computational complexity of F-OTCE is $O(mn \max(d, k))$, where $k$ is the number of Sinkhorn iterations in the OT computation. Specifically, the worst case complexity of computing the cost matrix between source and target samples is $O(md^2)$. Solving the OT problem by Sinkhorn algorithm with $\epsilon$-accuracy has complexity $O(mn k^2 / (\epsilon \chi))$ [29], where $\chi = \sup_{(z_s, z_t) \in \mathbb{Z}^2} c(z_s, z_t)$ is the maximum cost between source and target sample features and $\lambda$ is the weighting coefficient of the entropic regularizer. In practice, we usually set a constant parameter $\lambda$ and a stopping criteria with a maximum iteration. Finally, the conditional entropy computation takes $O(md)$ time.

Compared to F-OTCE, the additional computation of JC-OTCE lies in computing pair-wise label distances, which needs to solve $|\mathcal{X}_s| \times |\mathcal{X}_t|$ OT problems between the samples with given labels and finally produce Wasserstein distances.

The experimental computation time statistics of the empirical transferability and recent analytical transferability metrics LEAP, NCE, H-score, LogME, OTCE, and our proposed F-OTCE, JC-OTCE metrics are shown in Table II. Specifically, the empirical transferability is computed on GPU (NVIDIA GTX1080Ti) through retraining the source model on the target training data and then evaluating the transfer accuracy on the testing set. For analytical transferability metrics, we randomly select 1,000 instances from the testing set for computing transferability scores on CPU. Note that the time statistics already contained the time for evaluating features on the source model.

Results show that analytical transferability metrics are $\sim 90\times$ faster than the empirical transferability, without the requirement of GPU. Meanwhile, auxiliary-free metrics perform comparably on efficiency costing $\sim 10s$ for a pair of tasks. Although the original OTCE metric contains additional auxiliary time since it requires at least three auxiliary tasks with known empirical transferability to determine weighting coefficients, it is still worthy to use the OTCE metric for more accurate transferability estimation when there are many target tasks under the same cross-domain configuration needing evaluations.

#### C. Effect of Parameter $\gamma$

Here we investigate the effect of the hyper parameter $\gamma$ in JC-OTCE (see Equation (9)), which is a coefficient to balance...

Fig. 6. Visualization of the correlation between the transfer accuracy and transferability metrics, where the vertical axis denotes the transfer accuracy and the horizontal axis represents the transferability scores. Points in the figure represent different target tasks. Our JC-OTCE and F-OTCE metrics show significantly better correlation (more compact) with the transfer accuracy compared to state-of-the-art auxiliary-free metrics, especially under the challenging fixed category size setting. Meanwhile, the JC-OTCE metric performs comparably well with the auxiliary-based OTCE metric.

**D. Evaluation on OTCE-based Finetune**

In this part, we will evaluate the effectiveness of our transferability-guided transfer learning method OTCE-based finetune. An important application scenario of transfer learning is the few-shot classification problem, i.e., the target task only contains very few labeled training data, e.g., 1-shot, 5-shot, etc. Unlike previous meta learning based few-shot learning methods [30]–[33], where the data for meta-training and finetuning come from the same dataset (domain), we develop a more challenging few-shot classification benchmark under the cross-domain and cross-task setting.

**Task generation.** Specifically, we generate few-shot target tasks using the character recognition dataset Omniglot [34] and the natural image classification dataset MinImageNet [31], which are commonly-used benchmarks in few-shot learning. And we generate their respective source tasks using MNIST [35] and Caltech101 [36] datasets. The details of datasets are introduced in Table III, and examples are visualized in Fig. 8. We randomly generate 100 few-shot image classification tasks (5-way-5-shot) from each target dataset respectively.

**Transfer settings.** We train the source model (for transfer

learning approaches) or apply meta-training (for meta learning approaches) on the source dataset, and then finetune the pretrained model or apply meta-test on the target task. To make a fair comparison with previous few-shot learning methods, we first evaluate on the widely-used model architecture, denoted as Conv4 [30]–[33], which contains four convolutional layers and one fully connected layer as described in Table V. Besides, we further study the performance of our OTCE-based finetune algorithm using different model architectures including the famous LeNet [37] for character recognition (MNIST→Omniglot) and the ResNet-18 [28] for natural image classification (Caltech101→MiniImageNet).

During the training phase of the OTCE-based finetune algorithm, we first optimize the source feature extractor over the source and target datasets for one epoch with the source batch size 256 and the target batch size 25. An Adam optimizer is used with learning rate $= 0.0001$. Then we initialize the target model with the optimized source weights and continue the finetuning on the target training set for 300 epochs using the same optimizer supervised by the classification loss function of target data. We adopt the same finetuning strategy for the vanilla finetune method.

Results. Table IV presents that our proposed OTCE-based finetune method consistently improves the transfer accuracy of the vanilla finetuning under all transfer settings, with up to 4.41% accuracy gain. On the other hand, the vanilla finetune method even outperforms existing representative few-shot learning approaches including ProtoNet [32], MatchingNet [31], MAML [30] and RelationNet [33] under the cross-domain setting, indicating that current meta learning methods need further improvements to obtain a better cross-domain generalization capability.

Fig. 9 also visually demonstrates that our OTCE-based finetune method indeed improves both the transferability score and the transfer accuracy of the source model for most target tasks as expected. In short, for a given target task, our OTCE-based finetune algorithm is a simple but effective approach to improve the transferability of the source model and achieve more accurate classification results in the end.

VI. CONCLUSION

Transferability estimation under the cross-domain cross-task transfer setting is a practical but challenging problem in transfer learning. We propose a transferability-guided transfer learning framework which not only provides two accurate and efficient auxiliary-free transferability metrics F-OTCE...
accuracy of the source model with up to
with less restrictions and a higher efficiency. Meanwhile,
respectively. In particular, the robust JC-OTCE performs com-
include the additional label distance in computing data corre-
spondences such that JC-OTCE is more robust than F-OTCE
using the single sample distance, which trade-offs a minor efficiency drop for more robust transferability estimation under large domain shifts.

Our proposed F-OTCE and JC-OTCE metrics drastically reduce the computation time of the auxiliary-based OTCE from 43 minutes to 9.32s and 10.78s respectively, and they reduce the computation time of the auxiliary-based OTCE by large domain shifts.

The conditional entropy measures the predicted label uncertainty of the target task under the given pretrained source model and source data, which is negatively correlated with the ground-truth transfer accuracy such that it can be an accurate indicator of transferability. Furthermore, JC-OTCE
