Abstract

The use of counterfactual explanations (CFXs) is an increasingly popular explanation strategy for machine learning models. However, recent studies have shown that these explanations may not be robust to changes in the underlying model (e.g., following retraining), which raises questions about their reliability in real-world applications. Existing attempts towards solving this problem are heuristic, and the robustness to model changes of the resulting CFXs is evaluated with only a small number of retrained models, failing to provide exhaustive guarantees. To remedy this, we propose the first notion to formally and deterministically assess the robustness (to model changes) of CFXs for neural networks, that we call Δ-robustness. We introduce an abstraction framework based on interval neural networks to verify the Δ-robustness of CFXs against a possibly infinite set of changes to the model parameters, i.e., weights and biases. We then demonstrate the utility of this approach in two distinct ways. First, we analyse the Δ-robustness of a number of CFX generation methods from the literature and show that they unanimously host significant deficiencies in this regard. Second, we demonstrate how embedding Δ-robustness within existing methods can provide CFXs which are provably robust.

1 Introduction

Ensuring that machine learning models are explainable has become a dominant goal in recent years, giving rise to the field of explainable AI (XAI). One of the most popular strategies for XAI is the use of counterfactual explanations (CFXs) (see [Stepin et al., 2021] for an overview), favoured for a number of reasons including their intelligibility [Byrne, 2019], appeal to users [Barocas et al., 2020], information capacity [Kenny and Keane, 2021] and alignment with human reasoning [Miller, 2019]. A CFX for a given input to a model is defined as an altered input such that the model, when assigned the altered input, gives a different output to that of the original input. Consider the classic illustration of a loan application, with features unemployed employment status, 25 years of age and low credit rating, being classified by a bank’s AI model as rejected. A CFX for the rejection could be an altered input where a medium credit rating (with the other features unchanged) would result in the loan being accepted, thus giving the applicant an idea of what is required to change the output. Such correctness of the modified output in attaining an alternative value is the basic property of CFXs, referred to as validity, and is one of a whole host of metrics around which CFXs are designed.

Our main focus in this paper is the metric of robustness. This is most often defined as robustness to input perturbations, i.e., the validity of CFXs when perturbations are applied to inputs [Sharma et al., 2020]. While this notion is useful, e.g., for protecting against manipulation [Slack et al., 2021], other forms of robustness can be equally important in ensuring that CFXs are safe and can be trusted. Robustness to model changes, i.e., the validity of CFXs when model parameters are altered, has thus far received little attention but is arguably one of the most commonly required forms of robustness, given that model parameters change every time retraining occurs [Rawal et al., 2020]. Indeed, if a CFX is invalidated with just a slight change of the training settings as in, e.g., [Dutta et al., 2022], we may question its quality in terms of real-world meanings. Consider the loan example: if, after retraining, the loan applicant changing their credit rating to medium no longer changes the output to accepted (thus invalidating the CFX), the CFX was not robust to the model changes induced during retraining. In this case, it might be argued that the bank should have a policy to guarantee that this CFX remain valid regardless, but this may have unfavourable consequences for the bank. Therefore, it is desirable that the CFXs account for such robustness.

Though some have targeted robustness to model changes, e.g., [Upadhyay et al., 2021; Dutta et al., 2022], these approaches are heuristic, and may fail to provide strong robustness guarantees. Formal methods for assessing CFXs along this metric are lacking. Indeed, there are calls for both formal explanations for non-linear models such as neural networks [Marques-Silva and Ignatiev, 2022] and standard-

∗These authors contributed equally.

1Referred to simply as robustness, unless otherwise specified, for brevity for the remainder of the paper.
ised benchmarking in evaluating CFXs [Kenny and Keane, 2021], voids we help to fill.

In this work we propose the novel notion of $\Delta$-robustness for assessing the robustness of CFXs for neural networks in a formal, deterministic manner. We introduce an abstraction framework based on interval neural networks [Prabhakar and Afzal, 2019] to verify the robustness of CFXs against a possibly infinite set of changes to the model parameters, i.e., weights and biases. This abstraction allows for a set of parameterisable shifts, $\Delta$, in the model parameters, permitting users to tailor the strictness of robustness (depending on the application).

For illustration, consider the loan example once more: the bank knows the scale of typical changes in their models and could encode this into $\Delta$. The bank would then be able to provide only $\Delta$-robust CFXs such that they are valid under any expected model shift during retraining (and if a model shift exceeds $\Delta$, they would have been alerted to this fact). It can be seen, even from this simple example, that $\Delta$-robustness can provide priceless guarantees in high-stakes or sensitive situations. After covering related work (§2) and the necessary preliminaries (§3), we make the following contributions.

• We formally introduce $\Delta$-robustness of CFXs for neural networks and propose an abstraction framework based on interval neural networks to reason about it (§4).

• We analyse the $\Delta$-robustness of several CFX approaches in the literature, demonstrating the utility of the notion and the lack of robustness in these methods (§5.2).

• We demonstrate how the verification of $\Delta$-robustness can be embedded in existing methods to generate CFXs which are provably robust (§5.3).

We then conclude and look ahead to the various avenues of future work highlighted by our approach (§6).

## 2 Related Work

### 2.1 Approaches to CFX Generation

The seminal work of [Wachter et al., 2017] casts the problem of finding CFXs for neural networks as a gradient-based optimisation against the input vector using a single loss function to address the validity of counterfactual instances, as well as their closeness to the input instances measured by some distance metric (proximity), while that of [Tolomei et al., 2017] defines CFXs for tree ensembles. Following these works, [Mothilal et al., 2020] include stochastic point processes and novel loss terms to generate a diverse set of CFXs. [Poyiadzi et al., 2020] formulate the problem into graphs and apply shortest path algorithms and find CFXs that lie in the data manifold of the dataset. [Van Looveren and Klaise, 2021] address the same problem using class prototypes found by variational auto-encoders (VAEs) or k-d trees. [Mohammadi et al., 2021] model the generation of CFXs as a constrained optimisation problem where a neural network is encoded using Mixed-Integer Linear Programming (MILP). Other methods that are able to generate CFXs for neural networks include that of [Karimi et al., 2020], which reduces CFX generation to a satisfiability problem, and that of [Dutta et al., 2020], which formulates the search for CFXs as a multi-objective optimisation problem.

Orthogonal to these studies, there are ongoing works that try to embed causal constraints when finding CFXs [Mahajan et al., 2019; Karimi et al., 2021; Kanamori et al., 2021]. Finally, there are a number of methods for generating CFXs for linear or Bayesian models, e.g., [Ustun et al., 2019; Albini et al., 2020; Kanamori et al., 2020], but we omit their details here since our focus is on neural networks.

### 2.2 Robustness of Models and Explanations

Robustness has been advocated in a number of ways in AI, including by requiring that outputs of neural networks should be robust to perturbations in the inputs [Carlini and Wagner, 2017; Weng et al., 2018]. Indeed, a number of works have drawn attention to the links between adversarial examples and CFXs, given that they solve a similar optimisation problem [Pawelczyk et al., 2022; Freiesleben, 2022]. The protection which robustness to input perturbations provides against manipulation has been shown to be important also as concerns explanations for models’ outputs [Slack et al., 2021] and a range of methods for producing explanations which are robust to input perturbations have been proposed, e.g., [Alvarez-Melis and Jaakkola, 2018; Sharma et al., 2020; Huai et al., 2022]. Meanwhile, [Qiu et al., 2022] use input perturbations to ensure that explanations are robust to out-of-distribution data, applying this technique to a range of XAI methods for producing saliency maps. A causal view is taken by [Hancox-Li, 2020] in discussing the importance of robustness to input perturbations in explanations for models’ outputs. Here it is argued that explanations should be robust to different models, not only changes within the model (as we target), if real patterns in the world are of interest. Ensuring that CFXs fall on the data manifold has been found to increase this robustness to multiplicity of models [Pawelczyk et al., 2022]. However, our focus is on formal approach to robustness when changing the model parameters, rather than the model itself. Notwithstanding the findings of recent works demonstrating the significant effects of changes to model parameters on the validity of CFXs [Rawal et al., 2020; Dutta et al., 2022], we are aware of only two works which target the same form of robustness we consider. [Upadhyay et al., 2021] design a novel objective for CFXs which incorporates the model shift, i.e., the change in a model’s parameters which may be, for example, weights or gradients. However, the approach is heuristic and may fail to generate valid robust CFXs (we will discuss other limitations of this approach later in §5.2). [Dutta et al., 2022] define the metric of counterfactual stability, i.e., robustness to model changes induced during retraining, before introducing an approach which refines any base method for finding CFXs in tree-based classifiers, rather than the neural networks we target. In addition, both works evaluate CFXs’ robustness by demonstrating CFXs’ validity on a small number of retrained models and cannot exhaustively prove the validity for other model changes.
3 Preliminaries

Notation. Given an integer $k$, let $[k]$ denote the set $\{1, \ldots, k\}$. Given a set $S$, let $|S|$ denote its cardinality. Given a vector $x \in \mathbb{R}^n$ we use $x[i]$ to denote its $i$-th component; similarly, for a matrix $w \in \mathbb{R}^n \times \mathbb{R}^m$, we use $w[i,j]$ to denote element $i, j$. Finally, we use $I(\mathbb{R})$ to denote the set of all closed intervals over $\mathbb{R}$.

Feed-forward neural networks. A feed-forward neural network (FFNN) is a directed acyclic graph whose nodes are structured in layers. Formally, we describe FFNNs and the computations they perform as follows.

Definition 1. A fully-connected feed-forward neural network (FFNN) is a tuple $\mathcal{M} = (k, N, E, B, \Omega)$ where:

- $k$ is the depth of $\mathcal{M}$;
- $(N, E)$ is a directed graph;
- $N = \bigcup_{i=0}^{k+1} N_i$ is the disjoint union of sets of nodes $N_i$;
- we call $N_0$ the input layer, $N_{k+1}$ the output layer and $N_i$ hidden layers for $i \in [k]$;
- $E = \bigcup_{i=1}^{k+1} (N_i - 1 \times N_i)$ is the set of edges connecting subsequent layers;
- $B : (N \setminus N_0) \to \mathbb{R}$ assigns a bias to nodes in non-input layers.

$\Omega : E \to \mathbb{R}$ assigns a weight to each edge.

In the following we use $a_{i,j}$ to denote the value of the $j$-th node in layer $N_i$ and let $V_i = [v_{i,1}, \ldots, v_{i,|N_i|}]$. Furthermore, we use $B_i$ to denote the vector of biases assigned to layer $N_i$ and $W_i$ to denote the matrix of weights assigned to edges between two nodes belonging to subsequent layers $N_{i-1}, N_i$, for $i \in [k+1]$.

Definition 2. Given an input $x \in \mathbb{R}^{|N_0|}$, an FFNN $\mathcal{M}$ computes an output $\mathcal{M}(x)$ defined as follows. Let:

- $V_0 = x$;
- $V_i = \sigma(W_i \cdot V_{i-1} + B_i)$ for $i \in [k]$, where $\sigma$ is an activation function applied element-wise.

Then, $\mathcal{M}(x) = V_{k+1} = W_{k+1} \cdot V_k + B_{k+1}$.

The Rectified Linear Unit (ReLU) activation, defined as $\sigma(x) = \max(0, x)$, is perhaps the most common choice for hidden layers. We will therefore focus on FFNNs using ReLU activations in this paper.

Definition 3. Consider an input $x \in \mathbb{R}^{|N_0|}$ and an FFNN $\mathcal{M}$. We say that $\mathcal{M}$ classifies $x$ as $c$, denoted (with an abuse of notation) $\mathcal{M}(x) = c$, if $c \in \text{arg max}_{c \in \{N_{k+1}\}} \mathcal{M}(x)[c]$.

For ease of exposition, we will focus on FFNNs used for binary classification tasks with $|N_{k+1}| = 2$. The same ideas also apply to other settings, e.g., multiclass classification or binary classification using a single output node with sigmoid activation, which we use in our experiments. More details on the latter can be found in Appendix B.

Counterfactual explanations. Consider an FFNN $\mathcal{M}$ trained to solve binary classification problems. Assume an input $x$ is given for which $\mathcal{M}$ produces a classification outcome $\mathcal{M}(x) = c$. Intuitively, a CFX is a new input $x'$ which is similar to $x$ and for which $\mathcal{M}(x') = 1 - c$.

Formally, existing literature characterises a CFX in terms of the solution space of a Constrained Optimisation Problem (COP) as follows.

Definition 4. Consider an input $x \in \mathbb{R}^{|N_0|}$ and a binary classifier $\mathcal{M}$ s.t. $\mathcal{M}(x) = c$. Given a distance metric $d : \mathbb{R}^{|N_0|} \times \mathbb{R}^{|N_0|} \to \mathbb{R}$, we can compute a CFX $x'$ as:

$$\arg\min_{x'} d(x, x')$$

subject to $\mathcal{M}(x') = 1 - c, x' \in \mathbb{R}^{|N_0|}$

A CFX thus corresponds to the closest input $x'$ (Eq. 1a) belonging to the original input space that makes the classification flip (Eq. 1b). A common choice for the distance metric $d$ is the normalised $L_1$ distance [Wachter et al., 2017]. Under this choice, CFX generation for FFNNs with ReLU activations can be solved exactly via MILP – see, e.g., [Mohammadi et al., 2021]. Finally, we mention that the optimisation problem can also be extended to account for additional CFX properties mentioned in §2.1.

We conclude with an example which summarises the main concepts presented in this section.

Example 1. Consider the FFNN $\mathcal{M}$ below where weights are as indicated in the diagram and biases are zero. The network receives a two-dimensional input $x = [x_0, x_1]$ and produces a two-dimensional output $y = [y_0, y_1]$. We assume hidden layers use ReLU activations.

![Diagram of FFNN](image)

The symbolic expressions for the output components are $y_0 = \max(0, x_0 - x_1)$ and $y_1 = \max(0, x_1 - x_0)$.

Given a concrete input $x = [1, 2]$, we have $\mathcal{M}(x) = 1$. Assume a CFX is computed as $x' = [2.1, 2]$; the classification outcome is now $\mathcal{M}(x') = 0$.

4 $\Delta$-Robustness via Interval Abstraction

The COP formulation of CFXs presented in Definition 4 focuses on finding CFXs that are as close as possible to the original input. The rationale behind this choice is that changes in input features suggested by minimally distant CFXs likely require less effort, thus making them more easily attainable by users in real-world settings. However, it has been shown [Rawal et al., 2020; Dutta et al., 2022] that slight changes applied to the classifier, e.g., following retraining, may impact the validity of CFXs, particularly those which are
can we generate useful CFXs for FFNNs that are provably robust to model changes?

In the following we formalise the notion of robustness we target and introduce an abstraction-based framework to reason about this notion in CFXs for FFNNs. To this end, we begin by defining a notion of distance between two FFNNs.

**Definition 5.** Consider two FFNNs $M = (k, N, E, \Omega)$ and $M' = (k', N', E', \Omega')$. We say that $M$ and $M'$ have identical topology if $k = k'$ and $(N, E) = (N', E')$.

**Definition 6.** Let $M$ and $M'$ denote two FFNNs with identical topology. We define the $p$-distance between $M$ and $M'$, denoted $\| M - M' \|_p$, as:

$$\| M - M' \|_p = \left( \sum_{i=1}^{k+1} \sum_{j=1}^{[N_i]} \sum_{l=1}^{[E_i]} |W_i[j, l] - W'_i[j, l]|^p \right)^{\frac{1}{p}}$$

for $1 \leq p \leq \infty$.

Intuitively, $p$-distance compares the weight matrices of $M$ and $M'$ and computes their distance as the $p$-norm of their difference. Biases have been omitted from Definition 6 for readability; the definition can be readily extended to range over biases too, as is the case in our implementation. Using this notion we can characterise a model shift as follows.

**Definition 7.** A model shift is a function $S$ mapping an FFNN $M$ into another FFNN $M' = S(M)$ such that

- $M$ and $M'$ have identical topology;
- $\| M - M' \|_p > 0$, for $0 \leq p \leq \infty$.

Model shifts are typically observed in real-world applications when a model is regularly retrained to incorporate new data. In such cases, models are likely to see only small changes at each update. In the same spirit as [Upadhyay et al., 2021], we capture this with the following definition.

**Definition 8.** Given an FFNN $M$, we define the set of plausible model shifts as $\Delta = \{ S \mid \| M - S(M) \|_p \leq \delta \}$, for $\delta \in \mathbb{R}_{>0}$ and $0 \leq p \leq \infty$.

Plausibility implicitly bounds the magnitude of weight and bias changes that can be effected by a model shift $S$, as stated in the following.

**Lemma 1.** Consider a FFNN $M$ and a set of plausible model shifts $\Delta$. Let $M' = S(M)$ for $S \in \Delta$. The magnitude of weight and bias changes in $M'$ is bounded.

In essence, it is possible to show that each weight (and bias) can change up to a maximum of $\pm \delta$ following the application of any $S \in \Delta$. Proofs are provided in Appendix A. In the following we use $W'_i[j, l] \triangleq W_i[j, l] - \delta$ and $W''_i[j, l] \triangleq W_i[j, l] + \delta$ to denote the minimum and maximum value each weight $W_i[j, l]$ can take in $M'$ for any $S \in \Delta$ and $i \in [k+1]$, $j \in [N_i]$ and $l \in [E_i]$. Equivalent notation is used for biases.

**Remark 1.** The bounds obtained in the proof of Lemma 1 are sound, but also conservative, i.e., they may result in models that exceed the upper bound on the $p$-distance for some choice of $p$. As an example, consider what happens when $W'_i[j, l] = W'[j, l]$ for each $i \in [k+1]$, $j \in [N_i]$, $l \in [E_i]$. These valuations satisfy Definition 8 when $p = \infty$, but fail to do so for, e.g., $p = 2$.

Despite weight changes being bounded, several different model shifts may satisfy the plausibility constraint. To guarantee robustness to model changes, one needs a way to represent and reason about the potentially infinite family of networks originated by applying each $S \in \Delta$ to $M$ compactly. We now introduce an abstraction framework that can be used to this end. We begin by recalling the notion of interval neural networks, as introduced in [Prabhakar and Afzal, 2019].

**Definition 9.** An interval neural network (INN) is a tuple $I = (k, N, E, B_T, \Omega_T)$ where:

- $k, N, E$ are as per Definition 1;
- $B_T : (N \setminus N_0) \rightarrow \mathbb{I}(\mathbb{R})$ assigns an interval-valued bias to nodes in non-input layers;
- $\Omega_T : E \rightarrow \mathbb{I}(\mathbb{R})$ assigns an interval-valued weight to each edge.

**Example 2.** The diagram below shows an example of an INN. As we can observe, the INN differs from a standard FFNN in that weights and biases are intervals.

The main difference between an FFNN and an INN is that weights and biases are now defined over intervals instead of single values, as shown in Example 2. Thus, the computation performed by an INN differs from that of an FFNN.

We use $v_{i,j} = [v_{i,j}^l, v_{i,j}^u]$ to denote the interval of values for the $j$-th node in layer $N_i$ and let $V_i = [v_{i,1}, \ldots, v_{i,N_i}]$. Equivalent notation is also used to denote interval-valued biases $B_i$ and weights $W_i$.

**Definition 10.** Given an input $x \in \mathbb{R}^{[N_0]}$, an INN $I(x)$ computes an output $I(x)$ defined as follows. Let:

- $V_0 = [x,x]$;
- $V_i = \sigma(W_i \cdot V_{i-1} + B_i)$ for $i \in [k]$.

Then, $I(x) = \sigma(W_{k+1} \cdot V_k + B_{k+1})$.

Definition 10 shows that an INN computes an interval for each output node. These intervals contain all possible values that each output can take under the valuations induced by $B_T$ and $\Omega_T$. As a result, we define the classification semantics of an INN as follows.

**Definition 11.** Consider an input $x \in \mathbb{R}^{[N_0]}$, a binary label $c$ and an INN $I$. We say that:

The main difference between an FFNN and an INN is that weights and biases are now defined over intervals instead of single values, as shown in Example 2. Thus, the computation performed by an INN differs from that of an FFNN.
Appendix A for proofs). For some values of \( x \) is defined as in Definition 14. Consider an input \( x \) be obtained from the set \( \{ x \mid M - S(M) \} \leq 0.1 \).

The symbolic expressions for the outputs of the INN are:

\[
y_0 = [0.9, 1.1] \cdot \max(0, [0.9, 1.1] \cdot x_0 + [-1, -0.9] \cdot x_1) + [-0.1, 0.1] \cdot \max(0, [-1, -0.9] \cdot x_0 + [0.9, 1.1] \cdot x_1)
\]

\[
y_1 = [0.9, 1.1] \cdot \max(0, [0.9, 1.1] \cdot x_1 + [-1, -0.9] \cdot x_0) + [-0.1, 0.1] \cdot \max(0, [-1, -0.9] \cdot x_1 + [0.9, 1.1] \cdot x_0)
\]

Given a concrete input \( x = [1, 2] \), we observe that \( I_{(M, \Delta)}(x) = 1 \) and therefore establish that \( \Delta \) is sound. We now check if the old CFX \( x' = [2, 1, 2] \) is still valid under the model shifts captured by \( \Delta \). The interval network outputs \( y_0 = [-0.031, 0.592] \) and \( y_1 = [-0.051, 0.392] \), indicating that \( I_{(M, \Delta)}(x') \neq 0 \). We thus conclude that \( x' \) is not \( \Delta \)-robust.

Assume now a different CFX \( x'' = [2, 6, 2] \) is computed. The outputs of \( I_{(M, \Delta)} \) for \( x'' \) are \( y_0 = [0.126, 1.160] \) and \( y_1 = [-0.106, 0.106] \). Since \( y_0 \neq y_0'' \), we have \( I_{(M, \Delta)}(x'') = 0 \), proving that the new CFX is \( \Delta \)-robust.

As shown in Example 3, the interval abstraction \( I_{(M, \Delta)} \) can be used to formally prove whether a given CFX \( x'' \) is robust all possible model shifts encoded by \( \Delta \). Indeed, when \( I_{(M, \Delta)}(x) = 1 \), we can conclude that the classification of \( x'' \) will remain unchanged for all \( \Delta \) in \( \Delta \). Checking Definition 11 requires the computation of the output reachable intervals for each output of the INN; for ReLU-based FFNNs, the MILP formulation of [Prabhakar and Afzal, 2019] can be used (see Appendix B).

\[\text{Example 3. We observe that the INN in Example 2 corresponds to the interval abstraction } I_{(M, \Delta)} \text{ of the FFNN } M \text{ introduced in Example 1, obtained for } \Delta \leq 0.1. \]

\[\text{The symbolic expressions for the outputs of the INN are:}
\]

\[\text{We illustrate the concepts introduced in the following example.}
\]

\[\text{Example 3. We observe that the INN in Example 2 corresponds to the interval abstraction } I_{(M, \Delta)} \text{ of the FFNN } M \text{ introduced in Example 1, obtained for } \Delta \leq 0.1. \]

\[\text{The symbolic expressions for the outputs of the INN are:}
\]

\[\text{Given a concrete input } x = [1, 2], \text{ we observe that } I_{(M, \Delta)}(x) = 1 \text{ and therefore establish that } \Delta \text{ is sound. We now check if the old CFX } x' = [2, 1, 2] \text{ is still valid under the model shifts captured by } \Delta. \text{ The interval network outputs } y_0 = [-0.031, 0.592] \text{ and } y_1 = [-0.051, 0.392], \text{ indicating that } I_{(M, \Delta)}(x') \neq 0. \text{ We thus conclude that } x' \text{ is not } \Delta\text{-robust.}
\]

\[\text{Assume now a different CFX } x'' = [2, 6, 2] \text{ is computed. The outputs of } I_{(M, \Delta)} \text{ for } x'' \text{ are } y_0 = [0.126, 1.160] \text{ and } y_1 = [-0.106, 0.106]. \text{ Since } y_0 \neq y_0'', \text{ we have } I_{(M, \Delta)}(x'') = 0, \text{ proving that the new CFX is } \Delta\text{-robust.}
\]

As shown in Example 3, the interval abstraction \( I_{(M, \Delta)} \) can be used to formally prove whether a given CFX \( x'' \) is robust all possible model shifts encoded by \( \Delta \). Indeed, when \( I_{(M, \Delta)}(x) = 1 \), we can conclude that the classification of \( x'' \) will remain unchanged for all \( \Delta \) in \( \Delta \). Checking Definition 11 requires the computation of the output reachable intervals for each output of the INN; for ReLU-based FFNNs, the MILP formulation of [Prabhakar and Afzal, 2019] can be used (see Appendix B).

\[\text{5 } \Delta\text{-Robustness in Action}
\]

In §4 we laid the theoretical foundations of an abstraction framework based on INNs that allows to reason about the robustness of CFXs compactly. In this section we demonstrate the utility thereof by considering two distinct applications:

- in §5.2, we show how the interval abstraction can be used to analyse the \( \Delta \)-robustness of different CFX algorithms across model shifts of increasing magnitudes;
- in §5.3, we propose an incomplete algorithm that uses interval abstractions to generate provably robust CFXs.

Our experiments, conducted on both homogeneous (continuous features) and heterogeneous (mixed continuous and discrete features) data types, show that our approach provides a measure for assessing the robustness of CFXs generated by other methods, but in contrast with them, it can generate CFXs with provable robustness guarantees.

\[\text{5.1 Experimental Setup}
\]

We consider four datasets with a mixture of heterogeneous and continuous data. We refer to them as credit (heterogeneous) [Dua and Graff, 2017], small business administration (SBA) (only continuous features used) [Li et al., 2018], diabetes (continuous) [Smith et al., 1988] and no2 (continuous) [Vanschoren et al., 2013].

Figure 1: Graphical representation of Definition 11. When \( I(x) = c \), the output range for class \( c \) is always greater than that of class \( 1 - c \) (the opposite holds for \( I(x) \neq c \)). Instead, if \( I(x) \approx c \) the two output ranges overlap, meaning that there may exist evaluations of weights and biases in the INN for which the predicted class is \( 1 - c \).

\[\text{Lemma 2. } I_{(M, \Delta)} \text{ over-approximates the set of models } M' \text{ that can be obtained from } M \text{ via } \Delta.
\]

Lemma 2 states that \( I_{(M, \Delta)} \) contains all models that can be obtained from \( \Delta \) and possibly more, but not fewer (see Appendix A for proofs). For some values of \( p \), the interval abstraction sometimes ceases to be an over-approximation and encodes exactly all and only the models that can be obtained from \( M \) via \( \Delta \), e.g., when \( p = \infty \).

A model shift \( S \), although plausible, may result in changes to the classification of the original input \( x \). When this happens, robustness becomes vacuous. This notion can be easily formulated in terms of the interval abstraction as follows.

\[\text{Definition 13. Consider an input } x \in \mathbb{R}^{[N_i]} \text{ and an FFNN } M \text{ s.t. } M(x) = c. \text{ Let } I_{(M, \Delta)} \text{ be the interval abstraction of } M \text{ under a set of plausible model shifts } \Delta. \text{ We say that } \Delta \text{ is sound if } I_{(M, \Delta)}(x) = c.
\]

We are now ready to formally define the CFX robustness property that we target in this work.

\[\text{Definition 14. Consider an input } x \in \mathbb{R}^{[N_i]} \text{ and an FFNN } M \text{ s.t. } M(x) = c. \text{ Let } I_{(M, \Delta)} \text{ be the interval abstraction of } M \text{ under a sound set of plausible model shifts } \Delta. \text{ We say that a CFX } x' \text{ is } \Delta\text{-robust if } I_{(M, \Delta)}(x') = 1 - c.
\]
The first two datasets contain known distribution shifts [Upadhyay et al., 2021]. We use $D_1$ ($D_2$) to denote the dataset before (resp. after) the shift. For the other datasets, we randomly shuffle the instances and separate them into two halves, again denoted as $D_1$ and $D_2$. For each dataset, we use $D_1$ to train a base model, and use instances in $D_2$ to generate model shifts via incremental retraining. We use $p = \infty$ to quantify plausible model shifts in all experiments that follow.

CFXs are generated using the following SOTA algorithms. We consider Wachter et al. [Wachter et al., 2017] (continuous data only), Proto [Van Looveren and Klaise, 2021] and MILP [Mohammadi et al., 2021]. The first two implement CFX search via gradient descent, while the third uses mixed-integer linear programming. We also include ROAR [Upadhyay et al., 2021], a SOTA framework for generating robust CFXs. More details about our experimental setup can be found in Appendix C.

5.2 Analysing $\Delta$-Robustness of CFXs

This experiment is designed to show that interval abstractions can provide an effective tool to analyse CFXs generated by SOTA algorithms. For each dataset, we identify the largest $\delta_{\text{max}}$ that results in a set $\Delta$ that is sound for at least 50 test instances in $D_1$. This is achieved by retraining the base model using increasingly large portions of $D_2$. We then use the CFX generation algorithms to produce 50 CFXs. Again, see Appendix C for details of both steps. We evaluate their robustness for model shifts of magnitude up to $\delta_{\text{max}}$ using $\Delta$-validity, the percentage of test instances whose CFXs are $\Delta$-robust.

Figures 2(a–d) report the results of our analysis. As we can observe, all methods generate CFXs that tend to be valid for the original model ($\delta = 0$), with ROAR having lower results in most cases. This is because ROAR approximates the local behaviours of FFNNs using LIME [Ribeiro et al., 2016], which may cause a slight decrease in the validity [Upadhyay et al., 2021]. However, the picture changes as soon as small model shifts are applied. $\Delta$-validity of Wachter et al., Proto and MILP quickly drops to zero even for model shifts of magnitude equal to 10% of $\delta_{\text{max}}$, revealing that these algorithms are prone to generating non-robust CFXs when even very small shifts are seen in the model parameters. ROAR exhibits a higher degree of robustness, as expected. However, its heuristic nature does not allow to reason about all possible shifts in $\Delta$, which clearly affects the robustness of CFXs as $\delta$ grows larger.

It can be easily seen that $\Delta$-robustness could be deployed as a filter, with customisable coarseness achieved by varying $\Delta$, when applied to methods which generate multiple CFXs, e.g., that of [Mothilal et al., 2020]. We demonstrate this application in Appendix D.

These experiments reveal many SOTA algorithms, including those that are designed to be robust, often fail to generate CFXs that satisfy $\Delta$-robustness. Thus, the problem of generating CFXs that are provably robust against model shifts remains largely unsolved.

5.3 Generating Provably Robust CFXs

We will now show how $\Delta$-robustness can be used to guide CFX generation algorithms toward generating explanations with formal robustness guarantees. Our proposed approach, shown in Algorithm 1, can be applied on top of any CFX generation algorithm and proceeds as follows. First, an interval abstraction is constructed for the FFNN $\mathcal{M}$ and set $\Delta$; the latter is then checked for soundness (Definition 13). Then, the search for a CFX starts. At each iteration, a CFX is generated using the base method and is tested for $\Delta$-robustness using the interval abstraction (Definition 14). If the CFX is robust, then the algorithm terminates and returns the solution. Otherwise, the search continues, allowing for CFXs of increasing cost to be found. These steps are repeated until a maximum number of iterations $t$ is reached. As a result, the algorithm is incomplete in that it may report that no $\Delta$-robust CFX can be found within $t$ steps (while one may exist for larger $t$).

**Algorithm 1 Generation of robust CFXs**

**Require:** FFNN $\mathcal{M}$, factual input $x$ s.t. $\mathcal{M}(x) = c$, set of plausible model shifts $\Delta$ and threshold $t$

**Step 1:** build interval abstraction $\mathcal{I}_{(\mathcal{M},\Delta)}$  

**Step 2:** check soundness of $\Delta$

**if** $\Delta$ is sound **then**

**while** iteration number $< t$ **do**

**Step 3:** compute CFX $x'$ for $x$ and $\mathcal{M}$ using base method

**if** $\mathcal{I}_{(\mathcal{M},\Delta)}(x') = 1 - \epsilon$ **then**

**return** $x'$

**else**

Step 4: relax cost of next CFX

Step 5: increase iteration number

**return** no robust CFX can be found

We instantiated Algorithm 1 using Wachter et al, Proto and MILP as base methods to generate CFXs. We use Wachter et al-R, Proto-R and MILP-R to denote the resulting CFX generation algorithms. For each dataset, we use the same $\delta_{\text{max}}$ identified in §5.2 to create sound sets of model shifts $\Delta$. The iterative procedure of Algorithm 1 generates CFXs of increasing cost until the target robustness $\Delta$ is satisfied. To increase the cost of CFXs for Wachter et al and Proto we iteratively increase the influence of the loss term pertaining to CFX validity. For MILP, instead, we require that the probability of the output produced by the classifier to subsequent CFXs increases at each iteration (all test instances are classified as class 0, and the desired class is class 1). More details are included in Appendix E.

Figures 2(e–h) show the results obtained. Overall, we can observe that Algorithm 1 successfully increases the $\Delta$-validity of CFXs generated by base methods (compared with Figures 2(a–d)). MILP appears to be the best performing algorithm, generating CFXs that always satisfy the given robustness target. The robustness of CFXs computed with Wachter et al and Proto also drastically improves across different datasets. In some cases our algorithm fails to produce robust CFXs, yet a considerable improvement in robustness can be observed (compare, e.g., Figures 4a and 2e). Interestingly, simply by altering the hyperparameters of the methods that were not specifically designed for the robustness purposes, they produced more robust results than ROAR.
Figure 2: Evaluation of $\Delta$-validity. (a-d, see §5.2): SOTA algorithms fail to generate completely robust CFXs as $\delta$ increases. (e-h, see §5.3): Embedding $\Delta$-robustness in the search process of the same algorithms results in more provably robust CFXs.

Table 1 reports the results obtained for this second set of experiments. We observe that enforcing $\Delta$-robustness, even for small $\delta$s, can considerably improve the validity of CFXs in the presence of larger model shifts. Indeed, Algorithm 1 increases the number of CFXs that remain valid after retraining by 68 – 100%. This improvement comes at the expense of $t_1$ distance, which often increases wrt the base methods. This phenomenon has already been observed in recent work [Dutta et al., 2022], where robust CFXs for tree classifiers were up to seven times more expensive than the non-robust baseline. The lof score of CFXs tends to remain unchanged from the base methods in many cases. However, for some combinations of algorithms and datasets, the score drops considerably, suggesting that a better strategy to generate subsequent CFXs may exist. Finally, we can observe that our approach often outperforms ROAR, producing CFXs that retain a higher degree of validity after retraining.

6 Conclusions

Despite the great deal of attention which CFXs in XAI have received of late, state-of-the-art approaches fall short of providing formal robustness guarantees on the explanations they generate, as we have demonstrated. In this paper we proposed $\Delta$-robustness, a formal notion for assessing the robustness of CFXs with respect to changes in the underlying model. We then introduced an abstraction-based framework to reason about $\Delta$-robustness and used it to verify the robustness of CFXs and to guide existing methods to find CFXs with robustness guarantees.

This paper opens several avenues for future work. Firstly,
while our experiments only considered FFNNs with ReLU activations, there seems to be no reason why interval-based analysis for robustness of CFXs could not be applied to a wider range of AI models. Secondly, it would be interesting to investigate probabilistic extensions of this work, so as to accommodate scenarios where robustness cannot be always guaranteed. Finally, our algorithm for generating $\Delta$-robust CFXs is incomplete; we plan to investigate whether our abstraction framework can be used to devise complete algorithms with improved guarantees.

Appendices

A Proofs

Proof of Lemma 1

Proof. Combining Definition 8 with Definition 6, we obtain:

\[
\left( \sum_{l=1}^{k+1} \sum_{j=1}^{N_l} \sum_{i=1}^{N_i} |W_{i,j,l} - W_{i,j,l}'|^p \right)^{\frac{1}{p}} \leq \delta
\]

We raise both sides to the power of \( p \):

\[
\left( \sum_{l=1}^{k+1} \sum_{j=1}^{N_l} \sum_{i=1}^{N_i} |W_{i,j,l} - W_{i,j,l}'|^p \right) \leq \delta^p
\]

where the inequality is preserved as both sides are always positive. We now observe this inequation bounds each addend from above, i.e.,

\[
|W_{i,j,l} - W_{i,j,l}'|^p \leq \delta^p
\]

Solving the inequation for each addend we obtain \( W_{i,j,l}' \in [W_{i,j,l} - \delta, W_{i,j,l} + \delta] \), which gives the result. \( \square \)

The same result applies to bias values, which were omitted from Definition 6 for clarity.

Proof of Lemma 2

Proof. Lemma 1 shows that each \( S \in \Delta \) maps each weight \( W_{i,j,l} \) (resp. bias \( B_i[j] \)) in \( \mathcal{M} \) into a closed bounded domain that we denoted as \( [W_{i,j,l}, W_{i,j,l}'] \) (resp. \( [B_i[j], B_i[j]'] \)), for \( i \in [k+1], j \in [N_l] \) and \( l \in [N_{l-1}] \). These domains are used to initialise the corresponding \( W_{i,j,l} \) in \( \mathcal{I}(\mathcal{M},\Delta) \), which therefore captures all models that can be obtained from \( \mathcal{M} \) via \( \Delta \) by construction. However, following Remark 1, \( \mathcal{I}(\mathcal{M},\Delta) \) may also capture additional models for which their \( p \)-distance from \( \mathcal{M} \) is greater than \( \delta \). \( \square \)

B Output Range Estimation for INNs

We use the approach proposed in [Prabhakar and Afzal, 2019] to compute the output reachable intervals for each output of the INN. The output range estimation problem for (ReLU-based) INNs can be encoded in MILP as follows.

The encoding introduces:

- a real variable \( x_{0,j} \) for \( j \in [N_0] \) used to model the input of the INN;
- a real variable \( x_{i,j} \) to model the value of each node in \( N_i \), for \( i \in [k+1] \) and \( j \in [N_i] \);
- a binary variable \( \delta_{i,j} \) to model the activation state of each node in \( N_i \), for \( i \in [k] \) and \( j \in [N_i] \).

Then, for each \( i \in [k] \) and \( j \in [N_i] \) the following set of constraints are asserted:

\[
C_{i,j} = \begin{cases} x_{i,j} \geq 0, x_{i,j} \leq M(1 - \delta_{i,j}), \\ x_{i,j} \leq \sum_{l=1}^{N_{i-1}} W_{i,j,l} x_{i-1,j,l} + B_i[j] + M\delta_{i,j}, \\ x_{i,j} \geq \sum_{l=1}^{N_{i-1}} W_{i,j,l} x_{i-1,j,l} + B_i[j] \end{cases}
\]

where \( M \) is a sufficiently large constant. Each \( C_{i,j} \) uses the standard big-M formulation to encode the ReLU activation [Lomuscio and Maganti, 2017] and estimate the lower and upper bounds of nodes in the INN.

Then, constraints pertaining to the output layer \( k+1 \) are asserted for each class \( j \in [N_{k+1}] \).

\[
C_{k+1,j} = \begin{cases} x_{k+1,j} \leq \sum_{l=1}^{N_{k+1}} W_{k+1,j,l} x_{k,j,l} + B_{k+1}[j], \\ x_{k+1,j} \geq \sum_{l=1}^{N_{k+1}} W_{k+1,j,l} x_{k,j,l} + B_{k+1}[j] \end{cases}
\]

The output range for a given input \( x_0 \) and each class \( j \in [N_{k+1}] \) can be computed by solving two optimisation problems that minimise (resp. maximise) variable \( x_{k+1,j} \) subject to constraints 2-3. For more details about the encoding and its properties we refer to the original work [Prabhakar and Afzal, 2019].

Multiclass classification The method proposed by [Prabhakar and Afzal, 2019] is directly applicable to the multiclass setting and does not require any change wrt to the original formulation. The semantics of an INN for multiclass problems can be obtained by extending Definition 11 as follows.

Definition 15. Consider an input \( x \in \mathbb{R}^{[N_0]} \), a label \( c \in \{1, \ldots, m\} \) and an INN \( \mathcal{I} \). We say that:

- \( \mathcal{I} \) always classifies \( x \) as \( c \), written \( \mathcal{I}(x) = c \), if \( v_{k+1,c}^u > v_{k+1,j}^u \) for all \( j \in \{1, \ldots, m\}, j \neq c \);
- \( \mathcal{I} \) may classify \( x \) as \( c \), written \( \mathcal{I}(x) \equiv c \), if \( v_{k+1,c}^u > v_{k+1,j}^u \) for all \( j \in \{1, \ldots, m\}, j \neq c \) and there exists a label \( j \) such that \( v_{k+1,j}^u > v_{k+1,c}^u \);
- \( \mathcal{I} \) never classifies \( x \) as \( c \), written \( \mathcal{I}(x) \neq c \), if there exists \( j \in \{1, \ldots, m\} \) such that \( v_{k+1,j}^u > v_{k+1,c}^u \), for \( j \neq c \).

The definition of \( \Delta \)-robustness transfers to the multiclass semantics straightforwardly; checking whether the robustness property holds simply requires to estimate lower and upper bounds for each output class (> 2) as needed.

Binary classification with a single output node As mentioned in the main text, we formalised our results in the context of binary classification implemented via FFNNs with \( |N_{k+1}| = 2 \). However, the most common way to implement such classifiers is to use FFNNs with a single output node with sigmoid activation. This ensures that the output of FFNNs is always in the range \([0,1]\) and allows for a probabilistic interpretation of its value. This is indeed the implementation we used in our experimental analysis.
The interval abstraction can also be applied to this setting, although with two minor modifications wrt the formalisation of §4:

- sigmoid activations cannot be directly encoded in the MILP framework used to estimate output ranges of the interval abstraction (cf. B). However, the sigmoid function is invertible over its entire domain; as a result, reasoning about $\Delta$-robustness can performed on the pre-activation value of the output node without changing its meaning, nor affecting its validity.
- As a result, the (pre-activation) output of the interval abstraction is compared to zero instead of the usual 0.5 threshold determining classification outcome for binary classification using sigmoid (see Figure 3 for a graphical illustration).

### C Experimental setup

**Datasets** For each dataset, we first remove not-a-number values. Then, depending on the actual meanings of the input variables, we categorise them into continuous, ordinal, discrete. For continuous features, we perform min-max scaling; for ordinal features with possible values $[k]$, we encode each value $i$ into an array of shape $(k,)$, with the first $i$ values being 1 and the rest being 0; we one-hot encode the discrete variables. We report the details of each dataset after such preprocessing in Table 2. For sba dataset, we only use the continuous features.

**Classifiers and training** We used the sklearn library (https://scikit-learn.org/stable/index.html) for training neural networks with 1 hidden layer. The hyperparameters include number of nodes in the hidden layer, batch size, initial learning rate. The final hyperparameters were found using randomised search and 5-fold cross validation on $D_1$ (we report the classifiers’ accuracy and macro-F1 in Table 3). Accuracy score was used as the model selection criterion. The classifiers with the optimal hyperparameters were then trained on 80% (the training set) of $D_1$, and evaluated on the remaining 20% (the test set).

Table 3: Classifier evaluations

**Baseline implementations**

- Wachter et al: we use the Alibi library implementation for the method (https://github.com/SeldonIO/alibi). For §5.2, we change the target_proba hyperparameter to values $[0.55 - 0.95]$ lower than default (1.0) to optimise proximity while maintaining a high validity.
- Proto: we use the Alibi library implementation. Hyperparameters of this method are the default values.
- MILP: we implemented Definition 4 for neural networks, which is also a simplified version of Algorithm 5, [Mohammadi et al., 2021] satisfying the same plausibility constraints in support of heterogeneous datasets.
- ROAR: we use their open-sourced implementation: https://github.com/AI4LIFE-GROUP/ROAR. The hyperparameters are set to default values.

**Evaluation metrics** Similar to [Dutta et al., 2022], we use the sklearn implementation of local outlier factor: https://scikit-learn.org/stable/modules/generated/sklearn.neighbors.LocalOutlierFactor.html. Parameters are set to default.

**Retraining and $\delta$ values** Our retraining procedure follows that of sklearn’s `MLPClassifier.partial_fit()` function. $\delta_{\text{max}}$ in §5.2 (also the target $\delta$ in §5.3) is obtained by the following procedures. Consider the base model trained on $D_1$, $M$, and the dataset to retrain on, $D_2$:

1. Obtain $\delta_u$ by retraining $M$ on $a\%$ (initially $a = 1$) of $D_2$: randomly select $a\%$ instances from $D_2$ and train on them. Repeat this step for 5 times and get 5 different retrained classifiers, $M'_i$, $i \in [5]$. Then, $\delta_u = \max\left(\{\|M - M'_i\|, i \in [5], p = \infty\}\right)$.
2. Test if model shift $\Delta$ built with $\delta_u$ is sound for at least 50 test instances in $D_1$.
3. If the condition in step 2 is satisfied, increase $\delta_u$ and repeat step 1 and step 2; if not, $\delta_{\text{max}} = \delta_u$.

In order to show how $\delta_u$ (obtained by step 1 above) changes as $a$ increases to 100%, we demonstrate the relationship under our settings in Figure 4. It is shown that $\delta_u$ values increase with slight fluctuations as $a$ increases, and the magnitudes depend on the classifier and the dataset. As can be observed, $\delta_{\text{100\%}}$ values are always greater than $\delta_{\text{max}}$, indicating that the model shifts obtained by retraining on 100% of $D_2$ exceeds those included in $\Delta$ built with $\delta_{\text{max}}$, as stated in §5.3. Indeed,
observing the vm2 results of MILP-R from Table 1 again, we find CFXs that are 100% $\Delta$-robust (as per Figures 2(e–h)) with a smaller $\delta$ are likely to also be robust to certain instances of $\Delta$ with a larger $\delta$.

### D Applying $\Delta$-Robustness as a Filter

Similar to evaluating robustness, our approach can also be used as a filter for provably robust CFXs when multiple CFXs are provided for each test instance. To this end, we consider the following setting similar to Appendix C: a neural network is trained on (half of) the HELOC dataset\(^2\) to predict whether an applicant can successfully repay the loan given 10 continuous-type credit history information. We consider 5 test instances who failed the loan approval and we generate a diverse set of 20 CFXs for each applicant using DiCE [Mothilal et al., 2020], resulting in a total 100 CFXs. We perform the retraining Step 1 for $a = 1 \ 100$, test and report how many CFXs are $\Delta$-robust for some $\delta$ values. We also include the number of valid CFXs on the base model ($\delta = 0$). Results are presented in Figure 5. The neural network classifier is trained using PyTorch, the training and retraining settings are implemented in the same way as those of sklearn. We reduced DiCE’s hyperparameters $proximity\_weight$ to 0.05 and $diversity\_weight$ to 1.0 to increase the influence of the prediction correctness loss term and obtain more valid CFXs.

Note that in §5.2 and §5.3 we only report $\delta$ values whose corresponding $\Delta$ is sound. However, the fact that $\Delta$ is not sound for an instance $x$ means that there exist some model shifts in $\Delta$ under which the classification result of the test instance will change, and in practice there could be only a few such model shifts. Therefore, it could be meaningful to also test such non-sound sets of model shifts, as is the case in this example. We observe that the number of robust CFXs decreases as model changes become larger. Our approach is able to filter out the non-robust CFXs at any given $\Delta$. In reality, as stated in §1, the explanation-providing agent will have an estimate of typical $\delta$ values retrained on certain amount of new data, and the time period to collect such new data. With our approach, the agent could select only the $\Delta$-robust CFXs,

---

---

Figure 4: Plots of $\delta$ values obtained by retraining on increasing portions of $D_2$ described in Step 1, on each dataset. The points highlighted in red in each subfigure corresponds to the $\delta_{\text{max}}$ in §5.2 (target $\delta$ in §5.3) and the corresponding retraining percentage of $D_2$. $\delta_{\text{max}}$ is the largest $\delta$ value that is sound to at least 50 test instances, as also noted in the horizontal axis labels.
and provide a better estimate of how long they are valid for.

E Hyperparameter Tuning for Base Methods

Concrete implementations of Step 4 in Algorithm 1 depend on each base methods’ tunable hyperparameters, and are different for Wachter et al.-R, Proto-R, and MILP-R. In this section we introduce detail Step 4 for each of these method.

Wachter et al. In the Alibi library implementation, the loss function of [Wachter et al., 2017] is:

\[ l(x, x') = (\sigma(\mathcal{M}(x')), y_t)^2 + \lambda L_1(x, x') \]

where \( \sigma(\mathcal{M}(x')) \) is the value of the neural network’s output node and \( \sigma \) is the sigmoid function. \( \sigma(\mathcal{M}(x')) \) can be interpreted as the probability of class 1. \( y_t \) is the target probability (of class 1) of the resulting CFX for Wachter et al.-R. In our setting where test instances are of class 0, \( y_t \) could take values \([0.5, 1.0]\), the lower \( y_t \) is, the easier it is to find a closer (measured by L1 metric) CFX. \( \lambda \) is the weight term for proximity.

We apply two nested outer loops in search of the optimal \( y_t \) and \( \lambda \) values to find robust CFXs. For each experiment, we start with the \( y_t \) value taken in the non-robust setting, increase \( y_t \) by 0.1 until it reaches 1.0. For each \( y_t \) to test, we try finding robust CFXs using \( \lambda \) values of \([0.01, 0.05, 0.1, 0.2]\), where 0.1 is the default value.

Proto. In the case of Proto, the loss term pertaining to prediction correctness in the Alibi library implementation is the difference between the output probability of the desired class and the output probability of the undesired class plus \( \kappa \) (default 0), a hyperparameter to control the impact of this loss term in the loss function. In Proto-R, we gradually increase \( \kappa \) by 0.1 until it reaches 1.0 at each iteration.

MILP. For MILP, referring to Definition 4, the \( \mathcal{M}(x') = 1 - c \) condition requires that the lower bound of the output interval be greater than zero which, after the sigmoid output activation, corresponds to a probability greater than or equal to 0.5 for class 1. In this case, this method mostly find CFXs that lie on the decision boundary of the classifier. In MILP-R,

\[ \epsilon \geq 0. \\
\]

At each iteration, we raise \( \epsilon \) by 0.2 until it reaches 20.

Concrete values of each of the parameters can be found in the experiments in the accompanying source codes.

Figure 5: Plots of number of \( \Delta \)-robust CFXs as \( \delta \) increases.
