Abstract

Minimum Bayesian Risk Decoding (MBR) emerges as a promising decoding algorithm in Neural Machine Translation. However, MBR performs poorly with label smoothing, which is surprising as label smoothing provides decent improvement with beam search and improves generality in various tasks. In this work, we show that the issue arises from the inconsistency of label smoothing on the token-level and sequence-level distributions. We demonstrate that even though label smoothing only causes a slight change in the token-level, the sequence-level distribution is highly skewed. We coin the issue distributional over-smoothness. To address this issue, we propose a simple and effective method, Distributional Cooling MBR (DC-MBR), which manipulates the entropy of output distributions by tuning down the Softmax temperature. We theoretically prove the equivalence between pre-tuning label smoothing factor and distributional cooling. Experiments on NMT benchmarks validate that distributional cooling improves MBR’s efficiency and effectiveness in various settings.

1 Introduction

Neural Machine Translation (NMT) (Bahdanau et al., 2014; Vaswani et al., 2017) has witnessed significant progress in recent years. It models the conditional probability distribution of target language candidates given a source sentence by a neural architecture model. For a well-trained NMT model, decoding algorithms select high-quality candidates according to the model distribution. The most commonly used decoding is Maximum-a-Posteriori decoding (MAP), which aims to find the most probable candidate (i.e., mode of the distribution). However, as revealed by recent studies (Stahlberg and Byrne, 2019), the mode is often inadequate and degenerate, which calls for new and effective decoding algorithms.

Minimum Bayesian Risk Decoding (MBR) (Kumar and Byrne, 2002; Eikema and Aziz, 2020) emerges as a promising alternative to MAP decoding, which seeks the candidate with the largest utility instead of the largest probability. Several advantages have been observed, such as being robust against domain shift (Müller and Sennrich, 2021) and avoiding beam search curse (Eikema and Aziz, 2021). With the help of neural metrics (Freitag et al., 2021), MBR exceeds the de facto MAP decoding algorithm – beam search, and achieves state-of-the-art performance.

Despite the above promises, one crucial issue is identified for MBR but not yet solved in literature: MBR performs poorly with models trained with label smoothing (Eikema and Aziz, 2020). We further find that the performance drops monotonically when increasing the label smoothing factor. (see Figure 1, under the experiment settings in Section 4.1). It is counter-intuitive since label smoothing increases the generality of various tasks (Szegedy...
et al., 2016; Chorowski and Jaitly, 2017) and provides steady improvements in various NMT benchmarks (Vaswani et al., 2017; Chen et al., 2018).

For the underlying reason, Eikema and Aziz (2020, 2021) argue that the MBR requires unbiased sampling, while our experiments show the setting is sub-optimal. In this paper, we investigate the root cause and address this issue – label smoothing benefits beam search but hurts MBR. We analyze the effect of label smoothing on the token-level and sequence-level distributions. We show that even though label smoothing only slightly softens the token-level distribution, this effect makes the sequence-level distribution highly skewed with lots of low-quality candidates. We call the issue distributional over-smoothness. Then, we quantify the distributional over-smoothness using token-level entropy and find that it correlates well with MBR’s performance.

As beam search makes use of token-level distribution and MBR relies on sequence-level distribution, we propose a simple and effective approach, Distributional Cooling MBR (DC-MBR), which sharpens models’ distribution by cooling down the Softmax temperature. It corrects the skewed sequence-level distribution and avoids sampling from candidates that the model is not confident with. We theoretically prove that the optimal solutions of label-smoothed cross entropy can be transferable by adjusting Softmax temperature values after training. This validates that distributional cooling is a reverse process of label (un-)smoothing and can safely recover from the distributional over-smoothness without extra training.

Empirically, we conduct experiments on three NMT benchmarks, WMT2020 En-De, WMT20 De-En, and WMT16 En-Ro. The benefits of our method can be seen from two perspectives: (1) Effectiveness: Our approach significantly improves MBR’s performance in both models trained with (+17.3 BLEURT Scores) and without label smoothing (+1.4 BLEURT Scores). (2) Efficiency: To achieve the same performance, our method achieves a 25x speedup compared with the original MBR1.

2 Related Work

Label smoothing First introduced by Szegedy et al. (2016), label smoothing is designed to improve the generality of neural models by replacing the one-hot targets with smoothed targets. It has shown to be effective in various NLP tasks (Szegedy et al., 2016; Chorowski and Jaitly, 2017; Pereyra et al., 2017), and provides a steady performance gain in machine translation (Vaswani et al., 2017; Chen et al., 2018). Müller et al. (2019) first study the effectiveness of label smoothing with beam search and attribute its effectiveness to better calibration of the model’s predictions (Guo et al., 2017).

However, label smoothing is not always helpful. Meister et al. (2020) observe the case where higher entropy is detrimental to the performance of random sampling. Here we focus on label smoothing’s negative effect on MBR and attribute the issue to different behavior of label smoothing in sequence-level and token-level distribution. Further, we introduce distributional cooling that effectively resolve this issue.

Decoding Algorithms The dominant decoding method in NMT is Maximum-a-Posteriori (MAP) decoding, which seeks the hypothesis with the highest conditional probability. Among all MAP decoding methods, beam search is the de facto method in modern NMT systems. Many variants of beam search (Bahdanau et al., 2014; Wu et al., 2016; He et al., 2016; Yang et al., 2018; Murray and Chiang, 2018; Freitag and Al-Onaizan, 2017; Shu and Nakayama, 2018) are proposed to improve its performance. Other than beam search, exact decoding algorithms (Stahlberg and Byrne, 2019; Yan et al., 2021) utilize the depth-first search to find the mode or top candidates of the whole candidate space. However, the computational cost of exact search hinders its applications.

Minimum Bayesian Risk Decoding (MBR), originated from SMT (Kumar and Byrne, 2002; Smith and Eisner, 2006; Tromble et al., 2008), recently emerges as the new alternative to MAP decoding algorithm in NMT. MBR selects the candidates with the highest utility, e.g., an evaluation metric, instead of the highest probability, which may avoid degenerate problems with MAP. Early attempts to incorporate MBR into NMT mainly use the k-best list obtained via beam search (Stahlberg et al., 2017; Shu and Nakayama, 2017; Blain et al., 2017). Recently, Eikema and Aziz (2020) show that the mode of the NMT model is often inadequate, making MAP decoding undesirable. The authors claim that the model’s sequence distribution provides a good approximation for human trans-

1 Codes will be released soon.
We refer to $P(y)$ where $y$ can be factorised in an auto-regressive manner: \( P(y|\theta) = \prod_{i} P(y_i|y_{<i}, x; \theta) \). \( \tag{1} \)

We refer to \( P(y_i|y_{<i}, x; \theta) \) and \( P(y|x; \theta) \) as token-level distribution and sequence-level distribution, respectively. The token-level distribution \( P(y_i|y_{<i}, x; \theta) \) is derived using a Softmax function, \( o_i = f(y^i|y_{<i}, x; \theta), \) \( \tag{2} \)

\[
P(y_i|y_{<i}, x; \theta) = \frac{\exp o_i}{\sum_j |V| \exp o_j}, \tag{3} \]

where \( y^i \) is \( i \)-th token in the vocabulary \( V \), and \( o \) represents the output logits. The widely used objective for training an NMT model is the label-smoothed cross-entropy loss, defined as, \( L_{ls} = - \sum_i Q_{\lambda} \cdot \log P(y^i_i). \) \( \tag{4} \)

\( Q_{\lambda} \) is the \( \lambda \)-smoothed target distribution and its probability of the \( i \)-th token can be expressed as,

\[
Q_{\lambda}^i = \begin{cases} 
1 - \lambda & \text{if } y^i \text{ is golden token} \\
\frac{\lambda}{|V|-1} & \text{otherwise} 
\end{cases} \tag{5} \]

### 3.2 Decoding Algorithms

Given a model and an input, decoding algorithms select high-quality candidates from \( P(y|x) \).

**Maximum a Posteriori (MAP)** The standard decoding algorithm in NMT is MAP decoding, which finds the candidate with the highest sequence probability (mode of the sequence distribution),

\[
y^{MAP} = \arg\max_y P(y|x) \tag{6} \]

\[
y^{MAP} = \arg\max_{y_1, \ldots, y_T} \prod_{t} P(y_t|y_{<t}, x; \theta). \tag{7} \]

The exact solution of MAP is computationally costly due to NMT’s exponentially large search space. Hence, practitioners turn to beam search, a decoding algorithm that relied on greedy token selections.

**Maximum Bayesian Risk (MBR)** Recently, researchers find the mode of the model’s sequence distribution (i.e., MAP’s optimal solution) may be degenerate or even empty (Stahlberg and Byrne, 2019; Yan et al., 2021), which makes the mode a bad target. In contrast to MAP, MBR (Kumar and Byrne, 2002) chooses the candidate with the highest expected utilities:

\[
y^{MBR} = \arg\max_{h \in \mathcal{H}} \mathbb{E}_{r \in \mathcal{R}} \left[ u(h, r|x, \theta) \right]. \tag{8} \]

where the utility function \( u \) can be a certain evaluation metric measuring the similarity between a hypothesis \( h \) and a reference \( r \). The hypothesis space \( \mathcal{H} \) and reference space \( \mathcal{R} \) are sets of all possible translations. Clearly, the above formulation is also intractable as both spaces are prohibitively large. Recently, Eikema and Aziz (2020) propose a sampling-based approach that approximates both spaces with the help of the model distribution. The authors argue that the model distribution is a good approximation for human translations. Specifically, their approach relies on finite candidates sampled from the model’s distribution

\[
\gamma_{model} \sim \prod_{t} P(y_t|y_{<t}, x; \theta). \tag{9} \]
and uses these candidates as the pseudo references and hypotheses:

\[ \hat{\mu}_u(h; x, \theta) := \frac{1}{N} \sum_r u(h, r), \]  

\[ \hat{y}^{\text{MBR}} = \arg\max_{h \in \mathcal{Y}_{\text{model}}} \hat{\mu}_u(h; x, \theta), \]  

where \( N = |\mathcal{Y}_{\text{model}}| \) is the number of candidates sampled. In practice, the choice of the utility function can be NMT n-gram matching metrics like BLEU (Papineni et al., 2002), ChrF (Popović, 2015) or neural metrics like BLEURT (Sellam et al., 2020).

### 4 Analyses

#### 4.1 Experiment Setup

We conduct experiments on three NMT benchmarks: WMT 2020 English-German (En-De), WMT 2020 German-English (De-En), and WMT 2016 English-Romanian (En-Ro). For En-De and De-En, we apply the same filtering process described in Zeng et al. (2021) and get about 37M parallel sentence pairs, which are tokenized with Moses \(^2\) and segmented by byte pair encoding BPE (Sennrich et al., 2016) with 32000 merge operations. For En-Ro, we have 608k parallel sentences which are tokenized and segmented using the same tool as En-De and De-En. All models are trained for 300k steps. The batch size is 32k for En-De/De-En tokens and 16k for En-Ro. Hyper-parameters settings except label smoothing are the same as Vaswani et al. (2017). The statistics of datasets can be found in Table 1.

For MBR settings, our reported results rely on a candidate list of size 10/50. We use BLEURT v0.2 (Sellam et al., 2020) as our utility function as Freitag et al. (2021) to achieve state-of-the-art performance. We report BLEURT scores for WMT20 En-De and WMT20 De-En, and sacreBLEU for WMT16 En-Ro as its corpus is case insensitive and the BLEURT metric is trained on case-sensitive data. Results of other evaluation metrics can be found in Appendix C.

#### 4.2 Un-consistency between Token/Sequence Distributions

Extensive previous work (Szegedy et al., 2016; Chorowski and Jaitly, 2017; Pereyra et al., 2017; Vaswani et al., 2017) demonstrates the effectiveness of label smoothing across tasks. While it is also supposed to increase generality and improve MBR, it deteriorates MBR (Eikema and Aziz, 2021). One key distinction between MBR and beam search is that MBR relies on sequence-level distribution \( P(y|x) \) and re-ranks among sequence samples, while beam search generates tokens greedily from the token-level distribution \( P(y_t|y_{<t}, x) \).

Therefore, we explore the effect of label smoothing over the model’s sequence-level and token-level distributions.

Figure 2 demonstrates rankings of ground-truth tokens on the token-level distributions. We predict the teacher-forcing probabilities of reference tokens and investigate how the ranks of these tokens within the distribution \( P(y_t|y_{<t}, x) \) change with label smoothing factors. We can see that most of the reference tokens are ranked within the top 0-5, indicating that our models are well-trained. When

---

\(^2\)http://www.statmt.org/moses/
we increase the label smoothing factor, the rankings only change slightly. Specifically, the count of reference tokens in rank 0-5 slightly drops, and that in rank 45-|V| (tail of the token-level distribution) slightly increases. It implies that label smoothing makes the model mildly less confident at the token-level as intended. It improves the models’ generality and accords with our experiments in Figure 1 that label smoothing provides minor improvements with beam search.

In contrast to the minor impact at the token-level distribution, there lies a huge disparity regarding the sequence-level distribution. With the exact top-N (Yan et al., 2021) decoding algorithm, which is a DFS-based search algorithm equipped with a min-heap, we decode the topmost (i.e., top-20) sequences of the sequence-level model distribution. Figure 3 plots the translation qualities of these topmost sequences for models trained with and without label smoothing. As we can see, compared to the model without label smoothing, the model trained with label smoothing has more low-quality sequences in its top region of sequence-level distribution. It suggests that label smoothing skews the model distribution and gives poor sequences higher ranks/probabilities. This may relate to the well-known label bias problem (Lafferty et al., 2001), wherein the sampling process the model’s short-sighted decisions on certain steps lead to poor translations. This leads to low-quality hypotheses and reference spaces and explains MBR’s poor performance with label smoothing.

The above analyses of label smoothing explain our results in Figure 1. To further understand why a small distortion in the model’s token-level distribution results in a much skewed sequence-level distribution, we examine the auto-regressive nature of machine translation models. As a concrete example, suppose we have a sequence of 30 tokens. Given a perfectly trained model without label smoothing, each reference token would be predicted with a 100% probability and the whole reference sequence would also be predicted with a 100% probability. In contrast, with a model with label smoothing \( l = 0.1 \), each reference token receives a 90% probability, whereas the reference sequence as a whole receives only 90% \( |V| = 4\% \). The model would still be good if the probabilities are distributed to high-quality candidates. Unfortunately, the above analyses show it is not the case. We adopt the term distributional over-smoothness for this issue. In the next section, we discuss how to quantify distributional over-smoothness.

5 DC-MBR

5.1 Measuring Distributional Over-Smoothness Using Entropy

Measuring to what extent the model suffers from distributional over-smoothness is non-trivial, as the search space of sequence-level distribution is prohibitively large. We turn to a token-level measure that performs well empirically, the token distribution entropy,

\[
H = \sum_{i} P(y_i^t) \log P(y_i^t). \tag{12}
\]

The connection is straightforward. The lower the token level entropy is, the less probability mass is distributed from the golden reference.

To validate our measure, we conduct experiments on the WMT20 En-De task and investigate the relationship between entropy and MBR performance.

To control the entropy values, we train 45 Transformer-base models with various hyperparameters (i.e., \( \alpha \in [0.1, 0.9] \) and \( \beta \in [0.1, 0.5] \)) of generalized entropy regularizations (GER, Meister et al. 2020), where label smoothing is one of the special cases. We use a Transformer-base model with the same hyper-parameter setting following Vaswani et al. (2017) as our base model, and fine-tune the model for 10k more steps. Figure 4 plots the BLEURT scores against corresponding model entropy values. Our measure of distributional over-smoothness is a good proxy as it correlates strongly (-0.99) with the MBR performance. The model with smaller token distribution entropy...
suffers less from distributional over-smoothness and achieves a better performance with MBR.

5.2 Distributional Cooling for MBR

In order to mitigate the distributional over-smoothness and further improve MBR, it is essential to sharpen the model distribution. This is simply the reverse of label smoothing. While it can be achieved by training with negative entropy regularizations, it would require extra computational overhead and it would sacrifice the model’s performance with beam search.

Instead, we propose a simple and effective approach, Distributional Cooling for MBR (DC-MBR), which reduces the model’s token-level entropy by cooling down the distribution. Specifically, we manipulate the generation process of both hypothesis and reference spaces due to their distinct roles in MBR. See more discussion in Section 5.6.

Formally, we divide the logits $o$ by temperature $T$ before normalization,

$$P(y_t|y_{<t}, x; \theta, T) = \frac{\exp \frac{o_t}{T}}{\sum_j \exp \frac{o_j}{T}}.$$  \hspace{1cm} (13)

and generate candidates in hypothesis space and reference space with

$$Y_{\text{model}}^T \sim \prod_t P(y_t|y_{<t}, x; \theta, T).$$  \hspace{1cm} (14)

The computation of MBR becomes

$$\hat{\mu}_u(h; x, \theta) := \frac{1}{N} \sum_r Y_{\text{model}}^T \mu_u(h, r),$$  \hspace{1cm} (15)

$$\hat{y}^{\text{DC-MBR}} = \arg \max_{h \in Y_{\text{model}}^T} \hat{\mu}_u(h; x, \theta).$$  \hspace{1cm} (16)

We use separate temperatures $T_h$ and $T_r$ for the hypothesis and reference spaces due to their distinct roles in MBR. See more discussion in Section 5.6.

With distributional cooling, we model a label (un-)smoothing process, as it forces the model to focus on its most confident candidates and avoid distributing probability mass on unconfident ones. It is simple and easy to implement. It only modifies the decoding phase, which can be easily applied to off-the-shelf MT models and does not affect the model’s performance with beam search.

5.3 Equivalence between Label (Un-)Smoothing and Distributional Cooling

Aside from the intuitive connection, distributional cooling also theoretically connects with the label (un-)smoothing. In this section, we provide detailed proof.

**Proposition 1** The optimal solution of the model trained with label smoothing $\lambda$ is $\hat{P}_\lambda$ whose probability of $i$-th token is:

$$\hat{P}_\lambda^i = \begin{cases} 1 - \lambda, & y^i \text{ is golden token} \\ \lambda |W|^{-1}, & \text{otherwise} \end{cases}.$$  \hspace{1cm} (17)

Intuitively, this solution is straightforward since minimizing cross-entropy loss equals minimizing the Kullback–Leibler divergence between target distribution $Q$ and model distribution $P$. The loss achieves zero if and only if two distributions are the same.

With the assistance of Proposition 1, we can further derive the following lemma.

**Lemma 1** Given two models that achieve the optimal solutions with different label smoothing factors $\lambda_1, \lambda_2 < 1$, there exists a Softmax temperature factor $T = (\log \frac{1-\lambda_1}{\lambda_1})/(\log \frac{1-\lambda_2}{\lambda_2})$ that can transform $\hat{P}_{\lambda_1}$ to $\hat{P}_{\lambda_2}$.

The detailed proof for Proposition 1 and Lemma 1 can be found in Appendix.

The above Lemma proves that post-tuning the Softmax temperature is equivalent to pre-tuning the label smoothing factor. Thus, we can exactly manipulate the Softmax temperature to recover the over-smoothness brought by label smoothing, and, furthermore, improve the performance of MBR. This justifies our approach in that distributional cooling with a temperature $T < 1.0$ does not just make the model’s output distribution sharp in any direction. It transforms the distribution towards the optimal solution of a model trained by a smaller label smoothing factor.

5.4 Main Results

Table 2 and 3 show our results on three NMT benchmarks. We vary the label smoothing factor over two settings: low-cost ($N=10$) and high-cost ($N=50$). The default value of temperature is set to 0.5.

**DC-MBR mitigates distributional over-smoothness.** As shown in rows 2-4 in each sub-table, we confirm that models trained by label smoothing (‘+LS xx’) perform poorly with naive MBR. The performance drops drastically no matter the choice of the number of candidates or tasks. In contrast, DC-MBR (column Ours) achieves strong and consistent performance across different choices of label smoothing.
\begin{table}[h!]

\hline
\end{tabular}
\caption{(b) WMT20 German-English Task.}
\end{table}

Table 2: BLEURT scores for En-De and De-En. Gray: Models performs poorly with original MBR. We investigate two settings: Low cost, $N=10$, 100 BLEURT calls per sentence; High cost, $N=50$, 2500 BLEURT calls per sentence. Both $T_h$ and $T_r$ are set to 0.5.

DC-MBR improves over naive MBR. We compare the results of column MBR and column Ours. We observe a huge gap (+4.9 BLEURT score) in the low-cost scenario and a considerable gap in the high-cost scenario (+1.4-2.1 BLEURT score). Our results suggest that the widely used unbiased setting is sub-optimal, and the construction of hypothesis and reference space needs exploration.

DC-MBR significantly reduces the computational cost. A by-product of our approach is our method can achieve the same performance with much less computational cost, i.e., the number of candidates, and thus enable a much faster decoding process. Our low-cost result (68.8, ‘Transformer, Ours, $N=10$’) is comparable to that of original MBR’s high-cost result (68.7, ‘Transformer, MBR, $N=50$’). The computational cost is reduced from 2500 BLEURT calls to 100 BLEURT calls (25x speedup) to achieve the same performance, due to the quadratic nature of MBR. In addition, compared with other acceleration methods (Eikema and Aziz, 2021; Freitag et al., 2021), which mainly focus on truncating the hypothesis space or the reference space and accelerating the MBR computation process solely, our methods directly reduce the number of candidates needed and accelerate both candidate generation and MBR.

DC-MBR vs Beam Search. We compare beam search (‘BS’) with our approach, as beam search is the widely applied decoding algorithm in NMT applications. As we can see, our method can surpass beam search (65.0, ‘Transformer, BS’) even at the low-cost (68.8, ‘Transformer, Ours, $N=10$’) scenario. In addition, naive MBR (63.8, ‘Transformer, MBR, $N=10$’) with the same budget performs worse than beam search. The results indicate that our approach makes MBR more applicable in place of beam search in NMT applications, with lower costs and higher translation quality.

Label Smoothing cooperates with DC-MBR. Except that the results further corroborate our previous findings, we have one additional observation from Table 3: the model without label smoothing performs the worst with both beam search and DC-MBR. Models with larger label smoothing factors perform better. This indicates that label smoothing is still effective in preventing the model being over-confident, especially when the training set is small (608K). We recommend the usage of both label smoothing and DC-MBR, based on this observation.

5.5 Study on Number of Candidates

In our approach, we decrease the Softmax temperature to sharpen the token-level distribution. This operation may reduce the diversity of generated candidates. Thus, one possible concern is whether our method would limit the potential of MBR when using a large number of candidates.

In this section, we study MBR’s performance as the number of candidates increases (Figure 5). We
plot different temperature choices and report the corresponding BLEURT scores over WMT20 En-De. We present results with both models trained with and without label smoothing.

Given the model with label smoothing, distributional cooling is necessary. Even with 250 candidates sampled per sentence, our methods \((T < 1.0)\) strongly outperform the naive MBR \((T = 1.0)\) by a considerable margin. Given the model without label smoothing, our methods still significantly outperform naive MBR in most cases, except in the scenario of high costs (e.g., \(N=250\)), where a proper choice of temperature (e.g., \(T=0.6/0.8\)) is required. For both models, our approach helps MBR achieve strong performance at a low cost \((N=5,10)\).

In addition, we find that our approach improves with the number of candidates, indicating our approach retains the advantage of MBR of not suffering from the beam search curse problem (Koehn and Knowles, 2017b; Eikema and Aziz, 2021).

These results resolve the concern that sharpening model distribution would limit the gains with a large number of candidates.

5.6 Distinct Roles for \(\mathcal{Y}_h\) and \(\mathcal{Y}_r\)

In the above experiments, we use the same temperature to generate both the hypothesis and reference space. However, they have very different roles in MBR decoding. In this section, we study how they are affected by the temperature.

Figure 6 shows the choices of \(T_h\) and \(T_r\) for the hypothesis and reference space, respectively. Experiments are conducted on the valid set of WMT20 En-De. The model we use is the Transformer-base trained with label smoothing 0.1. As shown, \(T_h\) has a significant effect on the performance of MBR. The BLEURT score gap between the best \((T_h = 0.5)\) and worst settings \((T_h = 1.0)\) is about 20 points. A sharp hypothesis space is more favorable than a smooth one. On the other hand, a good \(T_r\) value also provides a considerable gain on the performance, about +1.5 BLEURT scores. Different from \(T_h\), a sharp reference space is not always the best choice. A \(T_r\) value that is too high or too low can result in a drop in BLEURT.

In order to further reveal the characteristics of both spaces, Figure 7 plots the quality and diversity for sampled candidates over different choices of temperature. We directly use the BLEURT score for quality, and the diversity score is defined as,

\[
\text{Div} = \frac{1}{|\mathcal{Y}|^2} \sum_{a \in \mathcal{Y}} \sum_{b \in \mathcal{Y}} \text{ChrF}(a, b),
\]

which is the average ChrF score (Popović, 2015) of each candidate against the others. We do not use neural metrics like BLEURT because they are trained to be robust against surface changes. In conclusion, the hypothesis space provides the possible candidates for translation, which should be of high quality and insensitive to diversity. In contrast, the reference space is responsible for the comprehensive evaluation of utilities, which should balance both quality and diversity.
6 Conclusion

We showed label smoothing hurts MBR performance due to the distributional over-smoothness it caused. We presented a simple and effective approach, DC-MBR, which manipulates the smoothness of MBR’s hypothesis space and reference space. In addition, we provided theoretical justifications for DC-MBR as a label (un-)smoothing technique after training.

Experimental results on large-scale NMT benchmarks demonstrated the effectiveness of our approach. DC-MBR is a simple and effective method that helps MBR avoid distributional over-smoothness. It can be equipped with off-the-shelf NMT models by achieving good performance with both beam search and MBR.

DC-MBR is effective in that it truncates the tail and forces MBR to focus on high-quality candidates. To utilize label smoothing’s power to improve generality with MBR or other sampling-based methods, we may need a normalization of label smoothing over sequence length. Nonetheless, it is beyond the scope of this paper, and we leave it for future directions.

7 Limitations

As the NLP community’s growing attention on the large-scale foundation models (Bommasani et al., 2021), one limitation of this work is that it has not explored the variety of these large models. For instance, recent models, like MASS (Song et al., 2019), GPT3 (Brown et al., 2020) and OPT (Zhang et al., 2022), have shown remarkable progress in multilingual few-shot translations. These foundation models could fit well with our methods. If these models are incompatible with MBR, re-training would be computationally costly. Thus, it is worth exploring how such large-scale foundation models perform with our MBR methods. We leave the MBR application with these large-scale foundation models as future work.

A  Derivation of Optimal Solutions

Even though in practice we solve the problem by gradient descent, the label smoothed cross entropy objective has an analytic optimal solution.

Recall that the label smoothed cross entropy loss is defined by,
\[ L_{ls} = - \sum_i Q^i_{\lambda} \cdot \log P^i \]
We want to see whether there exists a temperature value \( T \) which can transform \( \hat{P}_{\lambda_1} \) to \( \hat{P}_{\lambda_2} \).

First, with the Softmax formulation, we have,
\[ \sum_j \exp o^j_{gl} = 1 - \lambda_1 \]
where \( o_{gl} \) is the logit for golden target token. It is obvious that the non-target tokens share the same logit value, which we refer to \( o_{nt} \). Then, we have
\[ \sum_j \exp o^j_{gt} = 1 - \lambda_1 \]
\[ \sum_j \exp o^j_{gt} + (|V| - 1) \cdot \exp o_{nt} = 1 - \lambda_1 \]
\[ \Rightarrow \exp o_{gl} = 1 - \lambda_1 \cdot (|V| - 1) \cdot \exp o_{nt} \]
Therefore, if we can find a solution \( T \) that satisfies both,
\[ \exp o_{gl} = \frac{1 - \lambda_1}{\lambda_1} \cdot (|V| - 1) \cdot \exp o_{nt} \]
\[ \Rightarrow \frac{\exp o_{gl}}{T} = \frac{1 - \lambda_2}{\lambda_2} \cdot (|V| - 1) \cdot \exp o_{nt} \]
we obtain the optimal solution for label smoothing \( \lambda_2 \). By taking the logarithm of both equation 23 and 24, we obtain,
\[ \log \left( \frac{1 - \lambda_1}{\lambda_1} \right) = \log \left( \frac{1 - \lambda_2}{\lambda_2} \right) \]
\[ \Rightarrow T = \frac{(\log \left( \frac{1 - \lambda_1}{\lambda_1} \right))}{(\log \left( \frac{1 - \lambda_2}{\lambda_2} \right))} \]
Thus, for any given \( \lambda_1 \) and \( \lambda_2 \), we can have a temperature \( T \) that can transform the optimal solution for label smoothing \( \lambda_1 \) to \( \lambda_2 \).

B  Derivation of Equivalence between Label Smoothing and Temperature Rescaling

Here, we provide the detailed proof for the equivalence of post-tuning temperature and pre-tuning label smoothing factor. Give two models trained with label smoothing factor \( \lambda_1, \lambda_2 < 1 \). Based on Proposition 1, the optimal solutions are
\[ \hat{P}_{\lambda_1} = \left[ \frac{\lambda_1}{|V| - 1}, \cdots, 1 - \lambda_1, \cdots, \frac{\lambda_1}{|V| - 1} \right] \]
\[ \hat{P}_{\lambda_2} = \left[ \frac{\lambda_2}{|V| - 1}, \cdots, 1 - \lambda_2, \cdots, \frac{\lambda_2}{|V| - 1} \right] \]
### Table 4: Evaluation results with SacreBLEU and COMET on WMT20 English-German task. The experiment settings of Low and High are the same as that in main results. The utility function of MBR is BLEURT.
